August 2009, 134 pages

Finite element analysis using Cohesive Zone Method (CZM) is a commonly used method to investigate delamination in laminated composites. In this study, two plane strain, zero-thickness six-node quadratic (6-NQ) and four-node linear (4-NL) interface elements are developed to implement CZM. Two main approaches for CZM formulation are categorized as Unified Mode Approach (UMA) and Separated Mode Approach (SMA), and implemented into 6-NQ interface elements to model a double cantilever beam (DCB) test of a unidirectional laminated composite. The results of the approaches are nearly identical. However, it is theoretically shown that SMA spawns non-symmetric tangent stiffness matrices, which may lower convergence and/or overall performance, for mixed-mode loading cases. Next, a UMA constitutive relationship is rederived. The artificial modifications for improving convergence rates such as lowering penalty stiffness, weakening interfacial strength and using 6-NQ instead of 4-NL interface elements are investigated by using the derived UMA and the DCB test model. The modifications in interfacial strength and penalty stiffness indicate that the convergence may be improved by lowering either parameter. However, over-softening is found to occur if lowering is performed excessively. The morphological differences between the meshes of the models using 6-NQ and 4-NL interface elements are shown. As a consequence, it is highlighted that the impact to convergence performance and overall performance might be in opposite. Additionally, benefits of selecting CZM over other methods are discussed, in particular by theoretical comparisons with the popular Virtual Crack Closure Technique. Finally, the numerical solution scheme and the Arc-Length Method are discussed.

Keywords: Delamination, Cohesive Zone Method, Finite Element Method, Double Cantilever Beam Test, Arc-Length Method.

Yapışkan Alan Metodu (YAM) kullanılarak gerçekleştirilen sonlu eleman analizi, laminat kompozitlerdeki delaminasyonu incelemek için çok kullanılan bir metottur. Bu çalışmada, YAM' nu çalıştırmak için düzlem gerilim özellikli, sıfır yükseklikte altı-nodlu ikinci dereceli (6-Nİ) ve dört-nodlu lineer (4-NL) iki arayüz elemanı geliştirilmiştir. YAM yaklaşımları Birleşik Mod Yaklaşımı (BMY) ve Ayrık Mod Yaklaşımı (AMY) olarak sınıflandırılmış ve tekyönlü laminat kompozit yapılı Çift Dirsekli Kiriş (ÇDK) testi modellemesinde kullanılmak üzere 6-Nİ arayüz elemanlarına gömülmüştür. Yaklaşımlar için sonuçlar neredeyse aynıdır. Ancak, karışık-modlu yüklemelerde, AMY asimetrik tanjant katılık matrislerinin oluştuğu teorik olarak gösterilmiştir ki bu da yakınsaklık performansını ve/veya genel performansını karışık-modlu durumlarda düşürebilir. Takiben, BMY yapısal denklemleri yeniden çıkarılmıştır. Ara-yüz dayanımının zayıflatılması, ceza sertlik düzeyinin azaltılması ve 4-NL yerinde 6-Nİ ara-yüz elemanı kullanılması gibi yakınsaklık performansını artırıcı müdahaleler, çıkarılan BMY ve ÇDK testi modeli ile incelenmiştir. Ara-yüz dayanımının zayıflatılması ve ceza sertlik düzeyinin azaltılması modifikasyonlarının etkileri göstermiştir ki; herhangi birinin azaltılması durumunda yakınsaklık artabilmektedir. Ancak, fazlaca azaltma durumunda, aşırı-yumuşak sonuçlara ulaşılmıştır. 6-Nİ ve 4-NL arayüz elemanlarını kullanan sonlu eleman modelleri arasındaki morfolojik farklılıklar gösterilmiştir. Bunun sonucunda, yakınsaklık performansının ve genel performansın ters olarak etkilenebildiği ortaya konmuştur. Ek olarak, YBM metodunun seçilmesindeki faydalar, diğer metotlar üzerinden, özelliklede iyi tanınan Sanal Çatlak Kapama Tekniği ile teorik kıyaslama üzerinden tartışılmıştır. Son olarak, sayısal çözümlene ve Eğri-Uzunluğu Metodu tartışılmıştır.

Anahtar Kelimeler: Delaminasyon, Yapışkan Bölge Metodu, Sonlu Eleman Metodu, Çift Dirsek Kiriş Testi, Eğri-Uzunluğu Metodu.

ACKNOWLEDGMENTS

The author wishes to express his deepest gratitude to his supervisor Prof. Dr. Levend Parnas for their guidance, advice, criticism, encouragements and insight throughout the research.

The author would also like to thank Assoc. Prof. Dr. Gulio Alfano, from Brunel University, for his suggestions and comments.

CHAPTER 1

INTRODUCTION

1.1 Overview

Composite materials have gained popularity in high-performance products that need to be lightweight, yet strong enough to withstand high loading conditions such as aerospace components, boats, bicycle frames and racing car bodies. This is due to the fact that the technology combines various materials with their unique characteristics so as to get a superior combination. However, the complexity of the technology sometimes obstructs the understanding of failure modes and limits of the structural parts. Unavoidably, the limits of the composite structures should be identified well in order to use the technology efficiently and most importantly safely.

In the world of composites, *Laminated Composites* are the most widely used composites because of the familiar manufacturing and performance characteristics. The main feature of laminated composites is the stacking of *laminas* to ensure a global characteristic. Laminated composites are customized for planar structures to attain high strength allowables. However, the resin rich layer between the laminas has no reinforcement in through-the-thickness direction that sometimes yields separation of the laminas, causing a crack called *delamination crack* or simply *delamination*.

Form of delamination damage is particularly insidious, since the delamination crack may propagate undetected under the action of static or dynamic loads, leading to the ultimate failure of the component in addition to inducing reductions in stiffness and compressive load-carrying capacity of the laminate. Unlikely encountered in in-plane failures, the delamination would result in incapability of the structure only in compressive strength. Therefore, it could not be revealed until a compressive loading is applied at critical load or with special detection techniques. Consequently, the delamination analysis literally attracts researchers in composite technology due to its insidious characteristic.

Moreover, the delamination damage is frequently encountered in composite structures. A recent survey on problems concerning composite parts of civil aircrafts shows that delamination, caused by

impact, presents 60% of all damage observed in composite structures [105]. In a 1991 IATA (International Air Transport Association) survey, air carriers reported that about 40% of all damages come from platform or ground handling and maintenance [105]. Hence, the ease of delamination damage formation makes the phenomenon vital.

The delamination failure is predicted by using empirically determined design criteria – based on maximum allowable stresses/strains– during layout and construction of components made of fiber reinforced materials. For an optimal utilization, however, the potential offered by those materials as well as for the determination of inspection intervals, it is also essential to predict propagation delamination crack. In this study, the tool of *Damage Mechanics* is used for this purpose. This methodology is unified with Fracture Mechanics that result in **Cohesive Zone Method (CZM)**. In this approach, the delamination surface is modeled between individual laminas by *interface elements* of cohesive strengths which exhibit the approximate behavior of delamination cracks.

While the growth of delamination crack proceeds to the final, catastrophic failure, local changes in material stiffness due to strain weakening and the formation of new free surfaces of subcritical cracks are going to alter the load paths and result in load redistribution. The combined effects of the damage processes generally lead to nonlinearity in macroscopic traction-displacement constitutive relationships that are well defined by unique models called; Cohesive Zone Models. By embedding these models, one may take the delamination into account by quasi-static finite element analysis. For this purpose, MSC MARC 2005r3 [64] is used in the current study. Accordingly, appropriate interface elements and formulations are developed. However, the numerical solution procedures are the ones already included by MSC MARC.

The formulations of the cohesive interface elements comprise two main approaches encountered in the literature. The first one is Separated Mode Approach (SMA) considers mixed-mode delamination phenomenon with individual pure modes as proposed by Mi et al. [59], Alfano and Crisfield [1]. The next is the one considering the mixed-mode failure directly and actually, it is more widely used. It is called Unified Mode Approach (UMA) used by Ortiz and Pandolfi [68], Allix and Corigliano [3] and Camanho et al. [12]. These two concepts are theoretically compared in different mixed-mode ratios in terms of convergence performance and accuracy for the analytical approximation. To do that, the resulting tangent stiffness matrices formed by each approach are compared and contrasted.

In addition to the theoretical study, two finite interface elements are developed for numerical implementation. The most widely used interface elements; six-node quadratic and four-node linear elements, are both developed. In terms of accuracy and performance basis, two elements are compared. The convergence improving methods which are *decreasing penalty stiffness value* and

weakening interface strength. The investigation performed in the above items is done by finite element analysis of a unidirectional laminated composite Double Cantilever Beam (DCB) test.

1.2 Motivation

As mentioned in the introduction, delamination failure is a vital phenomenon that should be investigated deeply. From initiation to propagation, CZM promises visualization, accuracy and performance. In this sense, the capability of CZM makes it a senior candidate for the delamination finite element analysis.

However, there are many interface element types, approaches, models and artificial modifications that are all struggling to reach the most effective and accurate CZM interface element. On the other hand, in industry, engineers, who would like to apply this method, cannot always know the best way to use CZM. Therefore, a single CZM element, with both accurate and showing high performance in convergence issue, should be reached. Therefore, the main motivation behind this study is to reach most effective and accurate interface element addressing CZM.

1.3 Objective

The main objectives of this study are to develop and investigate CZM with interface finite elements in laminated composites. For the achievement of the study, four-node linear and six-node quadratic interface line elements with 2D plane stress assumption with zero-thickness capability are developed and implanted into MSC MARC 2005r3.

Two different CZM formulation approaches are categorized and named as Separated Mode Approach (SMA) and Unified Mode Approach (UMA). Both are theoretically compared in terms of their resulting tangent stiffness matrices in various mixed-mode ratios. For the accuracy point of view, both approaches are embedded into the developed six-node interface element and used in a unidirectional DCB test finite element model. On the other hand, the characteristics of resulting tangent stiffness matrices are investigated theoretically in order to point possible convergence problems for other mixed-mode ratios, which is out-of-scope of the DCB test. From the results of the theoretical and numerical comparison, one of the approaches is selected. The selected approach is re-derived and implemented into both four-node and six-node interface elements in order to proceed to further investigations. Both element types are applied into unidirectional DCB test model. The results are compared in terms of accuracy and convergence performances of the elements. The

element showing higher performance is taken and the effects of interfacial strength and penalty stiffness are investigated in order to find both accurate and high performance elements. Similarly, the tests are performed in the same DCB model. Although the capabilities of the elements involve mixed-mode loading, DCB test is selected in our study. The finite element analysis is performed in Total Lagrangian and the non-linear numerical solution technique is taken as the Spherical Arc-Length method.

In addition to the above applications, the advantage of using Spherical Arc-Length Method is discussed over Newton-Raphson method by stressing the importance of numerical solution scheme of CZM applications. Also, the benefits of selecting CZM for delamination analysis are discussed over other methods, especially by comparing with Virtual Crack Closure Technique (VCCT), theoretically

1.4 Content

Chapter 2 is dedicated as the “background” chapter of our study. This chapter investigates methodologies for the analysis of delamination growth in terms of both types of approaches for other procedures and CZM, respectively. In addition to the methodologies, contributing studies and examples are stated and explained for the CZM. All these sections are constructed in a comparative way among the methodologies and the example studies. However, the main emphasis is put on the comparison of the well known Virtual Crack Closure Technique (VCCT) and the CZM. Secondly, the delamination failure physics and the energy release rate in pure modes and mixed-mode are discussed in this chapter. It also deals with the delamination phenomenon in a general point of view, briefly. Yet, the main concern is the *energy release rate* in pure modes and mixed-modes.

Following the background chapter, Chapter 3 is devoted to the definitions and detailed discussion of CZM. Explicitly, this is the main section in that the theory is discussed. Through a brief historical background of CZM method, the theory and the physics behind the CZM is explained. Afterwards, the formulations of UMA are derived once and in our way. In addition, the derivation of element tangent stiffness matrix and internal force vector is presented. Regarding the method of UMA, the approach of SMA is given in Appendix B.

The most challenging part of the CZM method is the non-linear solution scheme. In Chapter 4, this problematic issue is tackled in a detailed manner. Besides, the *method of arc-length* is mainly discussed and explained. The discussion is literally based on the comparison between the other methods like well-known *Newton-Raphson* with the arc-length method. In addition to the analytical

point of view, since the arc-length method is selected as the nonlinear solver, thus, MSC MARC 2005r3's capability of the arc-length method and the way user interfere with parameters are also presented.

In Chapter 5, the element formulation of 6-node element with rotational capability is presented. The numerical integration scheme is the key point in accordance with the internal force distribution and tangent stiffness matrix. Therefore, the embedding section is discussed in detail. In addition, the benchmark test of DCB, test finite element model and the boundary conditions are introduced.

In Chapter 6, the results of the benchmark test are investigated in the scope of the objectives of our study. Finally, Chapter 7 is dedicated for the interpretation and Chapter 8 is for the further studies planned.

CHAPTER 2

REVIEW OF DELAMINATION PHENOMENON AND BACKGROUND

In this section, the advantages and disadvantages of the CZM are presented by discussing over other methods used in the literature for fracture mechanics simulations. In fact, this discussion puts the CZM method inside the “big picture” of the delamination simulation methods.

The delamination phenomenon is considered by categorizing the analysis types as *delamination initiation* and *delamination propagation*. The initiation part is going to have brief discussion in the way of presenting the methods that are proposed to be used. Since the propagation part is the main concern in our study, this part would involve more detailed discussion. Particularly, the literature survey for other methodologies is presented in this part.

In the explanation of the other methodologies, the main attention is given on the comparison with the current method of CZM in a competitive way. Especially, Virtual Crack Closure Technique (VCCT) is discussed and compared with CZM more elaborately since VCCT is the most popular method for the delamination growth simulations. At the same time, VCCT is the typical application of Fracture Mechanics (FM) based approaches [52]. Noting that FM methods are in competition with CZM, hence, it would better to take them into account so as to criticize CZM method objectively.

One of the fundamental knowledge for our investigation is types of failure modes. Therefore, the types of failure modes; *mode I*, *mode II*, *mode III* and *mixed-mode* phenomenon are explained, especially, in the way of revealing their impacts to our study. Since the numerical simulation performed is DCB test, analytical approximate solutions for mode I is given.

2.1 Cracks in Composites and Delamination

When a laminated composite panel is loaded, stresses are resolved excessively over inclusions or the features like notches and holes. Unlikely observed in the isotropic crystalline materials, there are various types of failures in composites. This is due to the heterogeneous structure of composites.

Therefore, it would be better to concentrate on typical cracks in composites and put the delamination aside.

Recalling the structure of a laminated composite, the plane defined by a constituent lamina corresponds to *plane of laminate*. Similarly, loads and stresses are “in-plane” only if they are applicable in that plane. For in-plane tension loading, there are various failure events possible to occur. The first damage is generally the matrix failure, at the locations where a stress concentration feature is located. One of those matrix failures could be *matrix tensile cracking*, especially in 90° plies (in transverse loading direction). Another can be *matrix shear cracking* between fibers, especially in off-axis 45° plies. In Figure 1a, one can distinguish 45° and 90° plies from the texture and corresponding oriented cracks relating to the mentioned failures.

Figure 1: (a) Matrix cracks in different orientations (b) Micro crack movement in 0° plies (c) H-Splitting failure [105]

On the other hand for 0° plies, the matrix shear cracks may originate as microcracks, and run in parallel between fiber pairs, in which they eventually become a *splitting crack* as shown in Figure 1b. Although these cracks are originated in the close vicinity of the stress concentrator features, eventually they tend to move away from the stress concentrator edges, followed by running in the direction of loading. Consequently, *H-type delamination* is visible as illustrated in Figure 1c. Such splitting cracks will be accompanied by delaminations between 0° plies and neighboring plies [105].

Hence, it can be noticed that even an in-plane crack may end up with a delamination. Unfortunately, there are no such studies accompanying the possible interactions of different crack types.

For compressive loads, still the basic features of splitting and delamination crack development process works, and still off-axis 45° plies are prone to have shear micro-cracking. Conversely, tensile matrix cracking in 90° plies tends to be suppressed [105]. However, the failure is never related to the fiber breakage in compressive loading. Instead of fiber failure, failure due to buckling, either at the global or local level, generally happens [72].

The damage modes discussed so far are *in-plane* failure modes that stay inside the lamina or goes through thickness of laminate. On the other hand, *delamination* failure corresponds to *out-of-plane* failure which can be simply defined as “debonding” of the constituent laminas resulting with separation as shown in Figure 2.

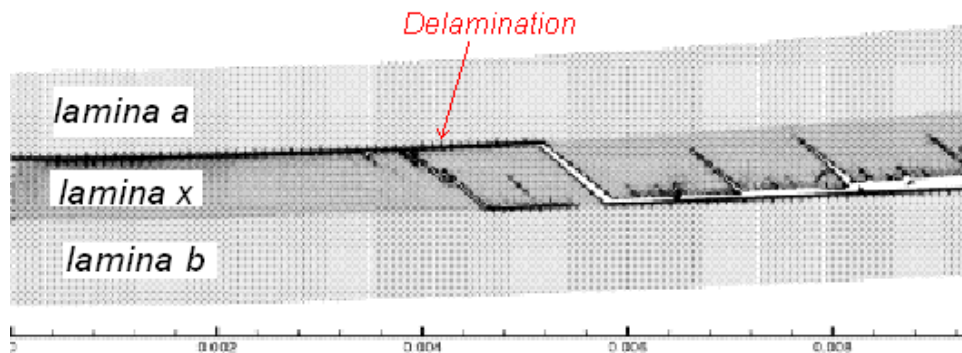

Figure 2: Delamination inside a laminate

Although the resemblance of the delamination is a crack, delamination phenomenon is not treated as easily as done for the in-plane cracks. For instance, the in-plane cracks are analyzed in terms of stresses which can be found easily by *Classical Laminated Plate Theory* (CLPT). On the other hand, the stresses are fully out-of-plane for the delamination cracks that would result in the surface between laminas. Therefore, delamination analysis literally depends on so called *interlaminar stresses*. Noting that, interface elements treat this phenomenon accurately as to be seen in the following chapters dedicated for the finite element implementation.

From a different point of view, delamination cracks are more insidious than in-plane cracks. Such behaviors make the delamination a dangerous phenomenon. The main reason for this conflict is lacking of any reinforcement in through the thickness direction. As a result, delamination cracks are

easier to form. Also, the delamination does not influence the response if the loading is tension. This characteristic makes the delamination insidious.

2.2 Delamination Initiation Analysis

Delamination initiation is generally analyzed by strength of material methods [95] which predicts the onset of delamination by using interlaminar point-wise maximum stresses/strains [12]. One could realize that the strength of material approach is a typical application that has been used so long for in-plane failure modes, successfully. For out-of-plane crack, delamination, however, the approach does not have such credibility because many experimental observations showed that using of a point-wise stress/strain criterion is not sufficient [13].

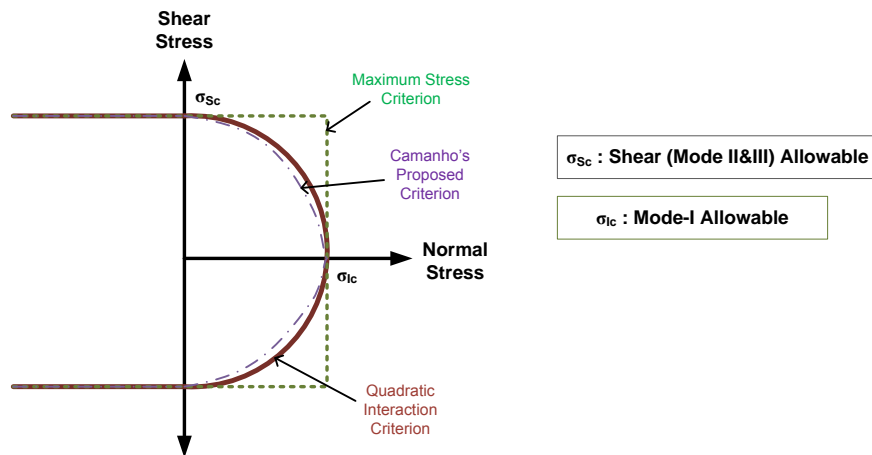

Figure 3: Delamination initiation criteria

Generally, *quadratic criterion* [106] is most widely used in mixed-mode initiation problems as shown in Figure 3. Besides, Camanho et al. [13,95] proposed a new criterion that seems more delicate. This approach takes the *total energy release rate*, G_T ($G_T = G_I + G_{II} + G_{III}$) and the mixed-mode effect into account in a different correlation. Noting that the quadratic criterion is the one used in our study since it is most widely used and agreed method in literature. Particularly, this initiation criterion is going to be discussed in detailed in the following sections.

Finally, an effective method has been developed as an amendment for the strength of material type methods by introducing a versatile parameter, called *characteristic length* [105]. Unfortunately, this

approach cannot be efficiently used in engineering applications, because the characteristic length parameter has not been proven to be a common material constant [105]. In other words, the length scale is such an empirical parameter that it is supposed to be obtained by experiments with the same stacking sequence.

2.3 Delamination Propagation Analysis

The other analysis type is *delamination propagation* which can be approached in two ways; the first is based on the direct application of *fracture mechanics*, while the second formulates the problem within the framework of *damage mechanics*. Although these two are the general approaches, there is a relatively new method that can neither be classified in fracture mechanics nor in damage mechanics types. This one is called *Crack Tip Element (CTE) / non Singular Field (NSF) method* [25], basically based on the well known *Classical Laminated Plate Theory (CLPT)*. Noticing that the details for the damage mechanics method are not discussed in this section and the fracture mechanics based methods will be discussed in detailed way under the umbrella of VCCT.

Delamination simulation procedures using FM, assume the existence of *singular stress field* around delamination crack tip [12]. In FM methods, the propagation is to be expected when a function of the energy release rates, G_I , G_{II} and G_{III} , along the delamination front locally exceeds a certain value, [51,86,90] which is called *fracture toughness*, G_c . Actually, this value can be regarded as a property of interface and depends on material and ply orientations of layers adjacent to the plane of delamination [51].

The difference among FM methods generally depends on the way of performing calculation of strain energy release rate [46,49,69,80,86]. For instance, VCCT calculates the energy release rate by using Irwin's *crack closure integral* [49], whereas, *J-integral method* [80], *virtual crack extension* [46], *θ -method* [35] and *stiffness derivative* [69] use similar or modified procedures.

On the contrary, it is possible to directly calculate SIF (or stress field) by directly using Finite Element Analysis (FEA) [90]. However, such direct FEM applications require specially designed crack-tip elements, especially unavoidable for complicated geometries [90]. SIF-based methods could be applied to predict the initiation of delaminations, and followed by any other method to describe delamination growth as conducted in [51].

Recently, a third type of method other than FM or DM, Crack Tip Element (CTE) / non Singular Field (NSF) type method has been developed by Davidson [25]. The method of CTE was developed

in order to deal with problems created by FM based methods. In the CTE/NFE method, the total strain energy release rate is obtained from well-known Classical Laminated Plate Theory, directly. The method is based on crack closure procedure that utilizes the near-tip plate theory in-plane forces and moments along with stiffness matrices of the intact region and two cracked regions [25]. Therefore, CTE/NSF approach is based on the assumption that Classical Laminated Plate Theory (CLPT) parameters completely characterize the near-tip loading and they are fully insensitive to the details of the local damage. However, this methodology mainly depends on a parameter requiring various tests that makes it hard to be applied in engineering applications easily. Even further, CTE/NSF method is rather a new method and further analyses should be required.

2.3.1 Cohesive Zone Method

Although CZM is going to be discussed in the dedicated chapter elaborately, for the general view of delamination analysis, the studies in the field of CZM are given. Moreover, in this section, the applications of *Cohesive Zone Method (CZM)* and distinguished studies are mainly discussed. Also, the main objective is to show the “big-picture” in that the cohesive zone modeling is more than capable to be used in engineering applications.

2.3.1.1 A Brief History of CZM

There was no model defining the actual crack tip behavior before the end of 50s. Up to that date, researchers had been using Linear Elastic Fracture Mechanics (LEFM) methods that assume an abrupt transition from stress free crack surface to the bulk material. Later, Dugdale [36] remarked *thin plastic zone* that is generated in front of the notch. Following Dugdale’s work, Barenblatt [15] introduced cohesive forces on a molecular scale in the zone that Dugdale had pointed out in order to solve the problem of equilibrium in elastic bodies with cracks in the way of the strength of the zone. In 1976, Hillerborg et al. [48] proposed a model similar to the Barenblatt model; however, the concept of tensile strength was introduced instead of molecular scale solution. Hillerborg’s model allowed existing cracks to grow and, even more importantly, allowed the initiation of new cracks, [48]. Actually, Hillerborg named the model as *fictitious crack model* which interestingly recalls the analogy of today’s *interface element method*. Actually, this was the stage, *cohesive zone method* was assumed to be born.

Figure 4: (a) Dugdale/Barenblatt type cohesive zone stress-displacement profile [59] (b) Typical stress-displacement profile used for cohesion analysis for ductile fracture [29] (c) Behavior used for cohesion analysis for quasi-brittle fracture [29]

The concept of CZM has been used by Needleman [66] to simulate fast crack growth in brittle solids. Needleman considered that cohesive zone models are particularly attractive when interfacial strengths are relatively weak compared with the adjoining material, as is the case in composite laminates. Unfortunately, the cohesive zone method has been used for the delamination of composite materials after mid 90's. Yet, the application based on the interface element formulation in finite element analysis is more recent.

2.3.1.2 Studies Taken as Basis in the Study

The studies taken as basis should possess robust formulations. Fulfilling that requirement, the following studies are the main ones that are taken as the main basis in our study.

One of the methods used in our study is proposed by Mi et al. [59] who performed CZM for the analysis of delamination in fiber composites. Mi et al. proposed the well known method for the mixed mode delamination in the scope of damage mechanics and indirectly using fracture mechanics in which the damage is defined as an *irreversible time parameter* which was maintained during the solution. The study is applied in the *Double Cantilever Beam* (DCB) test, the overlap specimen and *Mixed Mode Bending* (MMB) test by using finite element model for the capability and the reliability of the method. Consequently, the mixed mode interaction is analyzed. Typically, they compared the results with the analytical ones and the results showed quite good results. In addition, Mi et al. initiated discussions on the mesh size effect and the convergence related issues. Paralleling, they suggested and used the most effective non-linear solution method that is *modified cylindrical arc-length method* [19].

In the highlight of the study of Mi et al. [59], Alfano and Crisfield [1] have revisited CZM in a quite extensive manner. They have revisited the previous work of Mi et al. to make it more robust,

especially in the tangent stiffness matrix derivation from the constitutive relation. The constitutive relation is analytically related to all of the stages of the damage from initiation to the full separation. Even, the formulation became capable for both loading and reloading in any phase of the damage. Actually, the point they all consider the constitutive relationship is in pure mode displacements and critical energy release rate. Hence, our study refers their work as *Separated Mode Approach* (SMA).

On the other part, Camanho et al. [13] used CZM in terms of total displacement which works as a damage parameter at once. In addition to the former method, Camanho and Dávila [12] proposed a CZM model that uses Benzeggagh-Kenane (BK) type mixed-mode delamination growth criterion. Actually, as a contrast to SMA, Camanho et al. consider the formulation in terms of mixed-mode displacements and critical energy release rates, our study refers their approach as Unified Mode Approach (UMA). Also, it should be noted that there are many other authors [4,66,68] who have been already using this approach.

2.3.1.3 Selected Studies about CZM

Besides the studies taken as basis for our study, there are numerous works for enhancing and contributing to CZM. Moreover, it can be realized that the majority of the following studies are to enhance the convergence rates since perhaps this is a vital problem for CZM.

Following the studies [59] and [1], Alfano et al. [72] has augmented co-rotational formulation into the CZM method for the cases where there are *large displacements* and *large rotations* as seen in highly nonlinear cases like buckling. In fact, the formulation of CZM is based on the *small strain* approach. However, the delamination is a failure that generally there would be large displacements during the simulation that would yield considerable element coordinate rotations during numerical iterations. Consequently, the resulting *element stiffness matrix* would involve *initial stress stiffness matrix* in which the variation of *transformation matrix* cannot be neglected. Actually, the tangent stiffness matrix defined here is referred as *consistent tangent stiffness matrix*. To do that, they place a local coordinate frame on the interface element nodes in such a way that as the element rotates with the element, the coordinate frame rotates. As a result, Alfano et al. [72] has implemented the co-rotational formulation and applied it successfully in the buckling simulations. Our study does not use the co-rotational formulation since higher order terms can be neglected for the delamination growth in a simple DCB test.

Qui et al. [15] embedded the study of Mi et al. [59] to analyze the convergence effects by artificially varying the critical displacements instead. In fact, their study focuses on the application, detailed in

FE codes like finite element implementation and resulting influence to convergence. Therefore, this study has great contribution for our study as far as the implementation to FEA code is concerned.

One of the novel contributions interpreting the popular convergence issue is perhaps the study of Turon et al. [96]. According to their findings, the convergence problem mainly depends on the mesh density in the cohesive zone region as going to be examined in the following chapters. However, there is no accurate suggestion or requirement about the magnitude of the mesh density. Hence, they proposed an accurate mesh density related to the dimensions of cohesive zone. Their suggestion is illustrated in Figure 5 where it can be realized that the traction profile cannot be “reached” unless there is more than two elements. In addition to mesh density, one of the critical parameters affecting the numerical solution scheme is the *penalty stiffness*, which was also examined.

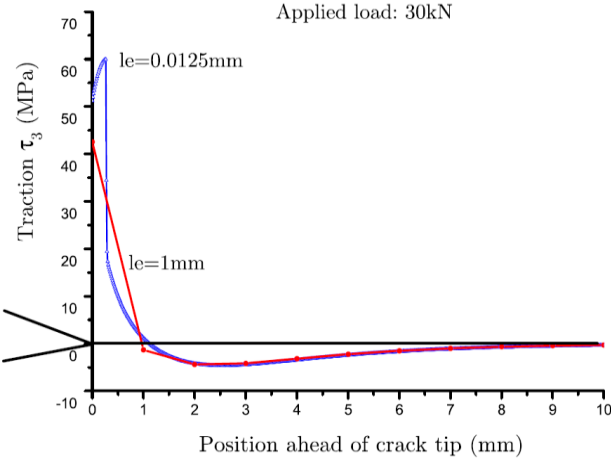

Figure 5: Mesh size and traction profile inside cohesive region [96].

In terms of the convergence issue, Harper and Hallet [43] analyzed the mesh size and the cumulative effect of interfacial strength. Their unique remark is about the interfacial strength that can be decreased artificially in the favor of convergence performance. However, as a limitation to that “trick”, Harper and Hallet [43] showed that there is literally a limit for the amount of decrease in the interfacial strength. They showed that excessively low interfacial strengths would affect the global response that even result *over-softening* of the structure. Therefore, they highlighted that the lowering of interfacial strength should be carefully done. Moreover in their study, for the first time, the length of the numerical cohesive zone was investigated in detail and compared to analytical solutions across a range of material and geometric parameters. As a result, a clear distinction was drawn between the physical and analytical cohesive zone lengths, and that is resulting from a numerical representation using interface elements.

The numerical solution scheme directly affects the convergence rates since the softening behavior of CZM method would yield sharp-snap backs. A quite extensive discussion about non linear solution procedures are considered by Alfano and Crisfield [2]. The key approach is enhancing the arc-length method, which is achieved by *localized control*. In addition to the locally controlled arc length method, advanced applications of line search methods are proposed. *Single Line Search Method* and *Double Line Search Method* are also considered.

From physical point of view, Yang and Cox [105] studied the subject in an extensive discussion in terms of all CZM critics in literature. Perhaps, the most distinguished contribution is to notice the physical phenomenon like *friction mechanisms* inside the CZM formulation to consider the actual response after the failure of the interface. As a result, Yang and Cox [105] proposed improving the CZM method in the favor of adding the relationship shown in right hand side behavior of Figure 6.

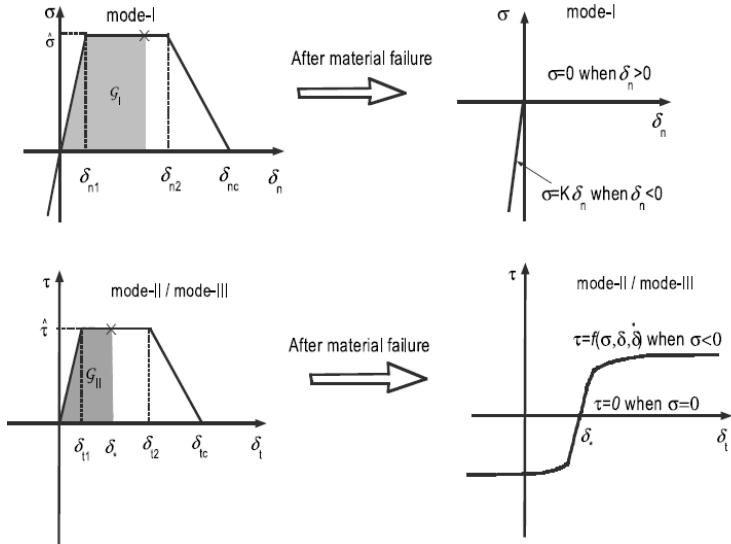

Figure 6: Contact (upper) and friction (lower) features are highlighted by Yang and Cox [105]

Although it is possible for the crack to propagate in all directions, only if there is an interface element. In other words, the crack propagation “freedom” is limited with the positions where the interface elements are located. In order to notice this problem, Tijssens et al. [94] modeled a *SEN-beam* with various modeling intensities as shown in Figure 7. The interface elements are placed among all continuum elements in the models. Consequently, the crack is able to follow any direction throughout the propagation. However, the results showed that the crack behavior is extremely sensitive to the model mesh density as could be traced from Figure 7. It is showed that the typical CZM could not be applied for large scale problems easily without having an adequate knowledge

about the possible crack propagation directions. Therefore, this study is very important because of remarking a lacking that might be come on the surface in three dimensional crack propagation analyses.

Figure 7: SEM beam modeling with different discretizations [94].

Another major aspect of the methodology is perhaps the implementation process inside finite element codes. Although our study and most of the studies so far are performed via *implicit* finite element solvers, there are also numerous applications that use *explicit* solvers [71,98]. In fact, the implementation into explicit FE packages has various advantages over the implicit ones. Actually, one major advantage is the convergence rate in which the numerical integrations would take place referring to *time*. However, there are two problems for embedding in explicit solvers [71,98]. The first one is the oscillations around the equilibrium curve as seen from Figure 8. The second problem actually arises due to the great convergence feature itself in that uses very small time steps that make sometimes hard to analyze an engineering problem. Although such problems occur, explicit applications are widely used, successfully.

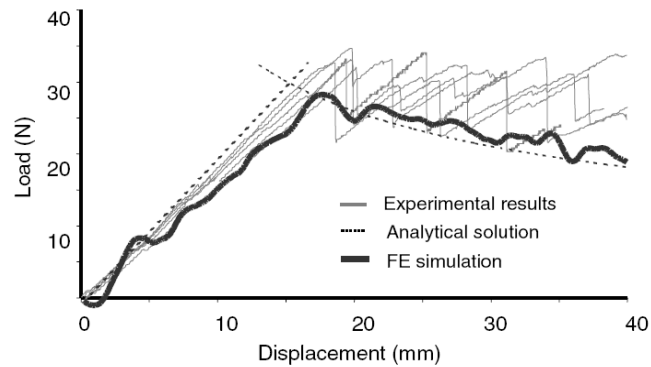

Figure 8: DCB test results obtained by using explicit FEA [98].

Moreover, the interface elements could be modeled as *springs* as done by Wisnom and Chang [77] for analyzing notched cross ply 0/90 laminates. They modeled splitting cracks and associated delaminations by using plane stress elements in FEM formulations to represent plies and nonlinear spring elements to represent crack wake processes. The spring elements were assigned a simple constitutive law, consisting of an initial linear rising part, a constant regime, and an abrupt loss of traction at a critical shear displacement. Yet, since out-of-plane stresses were not considered, the spring elements were consistently restricted to imposing shear tractions to oppose sliding crack displacements. Thus mode II and III crack displacements were possible, but not mode I. Similar to the spring modeling of interface [77], the interface elements could be modeled as *rods* that were suggested by Shahwan and Waas [89]. They proposed an interface model that could be used for compressive loading without characterizing the problem whether it is a buckling, post-buckling or static, conservatively. Moreover, the study was specialized for non self similar crack growth. However, the most distinguishing feature of the study is that the interface elements only require the mechanical properties (stiffness, thickness, etc.) of the laminate. They are adequate to totally characterize cohesive processes without resorting to any external criteria such as those from fracture mechanics concepts.

2.3.1.4 Engineering Applications

Today, nearly all well known commercial finite element packages have the cohesive element capability with appropriate 2D and 3D elements. Therefore, either pioneering applications or novel applications are going to be mentioned in this section.

Firstly, De Moura et al. [31] conducted the CZM method inside a *low impact damage* test resulting in delamination. They used 3D interfacial element with a rectangular specimen where the delamination is a “pea-nut” type at the corner of the specimen. Indeed, this study [31] is based on revealing the residual strength after the impact. Their main contribution is being the first study that CZM method has been embedded in an engineering application where the delamination growth is not a self similar one. In addition to this study, Aoki et al. [6] have also studied damage accumulation mechanism in cross-ply Composite Fiber Reinforced Fiber (CFRP) laminates by the low velocity impact.

As being one of the pioneering applications, Chen et al. [14,16] applied cohesive method in a repaired sandwich and stiffened panel which are all modeled and analyzed by using CZM interface elements. They showed that the methodology is capable to work well in actual engineering problems. The results showed that widely used bilinear constitutive relationship agrees quite well with test results. In addition, they noticed the effects of fracture toughness and interfacial strength effect to the global response just like done for the basic tests like DCB and MMB. Similarly, T.-S Han et al. [42] investigated feasibility of applying the cohesive crack propagation model as a method to simulate delamination propagation between a facesheet and a core in a honeycomb panel.

Instead of 3D brick interface elements, Davila et al. [27] suggested to use *interface shell elements*, modeled at the neutral planes of the plies, in 3D analysis. The shell cohesive elements have the same topology as three-dimensional elements, thus; they can be generated using any finite element pre-processor while zero-thickness cohesive elements for three dimensional elements cannot be generated with most pre-processors. In addition, the shell element modeling decreases the processing time of the finite element solver. The proposed model is applied to composite lugs and successful results are obtained.

In addition to the static loading, there are many applications of CZM modeling for fatigue crack growth in composite materials [11,83]. For instance, Robinson et al. [83] defines damage parameter – cycle relation that is mimicking well known Paris-Erdogan type crack equation. Since the damage is correlated with the cycles, it could be possible for the delamination to grow in the same manner as in isotropic materials.

There are various applications where different kinds of materials are analyzed as to be used in different engineering fields. For instance, Xu and Needleman [103], de Borst [37] and Elicses et al. [28] studied the fracture in concrete materials and macromolecular based polymer materials by using CZM method. Furthermore, Wei and Hutchinson [99], Thouless and Yang [104] applied the method for adhesively bonded joints. In addition, for bi-material interfaces Needleman [65] and Tvergaard

and Hutchinson, [97] applied the CZM successively and for the dynamic fracture of homogeneous materials, Needleman [66] studied the issue.

2.3.2 Fracture Mechanics Methods: Virtual Crack Closure Technique

Perhaps the most widely and successfully used technique for the delamination propagation is the Virtual Crack Closure Technique (VCCT) [52]. Also, since VCCT can be thought as “representative” of FM type methods, in order to compare damage mechanics method with fracture mechanics type methods, it would be convenient to discuss VCCT in more detailed manner. Noting that, the formulations given here is for the sake of showing the simplicity of the method. Moreover, after discussing VCCT, VCCT and CZM methods will be compared more objectively.

As an application of FM, Rybicki and Kanninen [86] have developed VCCT in which the procedure is mainly based on the calculation of the strain energy release rates at the crack tip [56]. VCCT is based on the same assumption of Irwin’s crack closure integral [49], in which the energy released in the process of crack expansion is equal to work required to close the crack to its original state as the crack extends by a small amount [67]. Actually, the direct application of the Irwin’s crack closure integral is generally referred as *crack closure method* [55].

The method has the assumption of non-altering state of the crack tip [86]. In words, the crack should grow in a self-similar manner when the crack extends from $a+\Delta a$ to $a+2\Delta a$ [55]. Therefore, the crack front is not allowed to be changed during the propagation. Under the scope of this requirement, the energy release rates can be computed from the nodal forces and displacements obtained from finite element model [13]. From Figure 9, the virtual work done by the force can be written as [52];

$$\Delta E = \frac{1}{2} \mathbf{F}(\boldsymbol{\delta}_u - \boldsymbol{\delta}_l) \quad (1)$$

Figure 9: Crack closure method: step 1 — the crack is closed; step 2 — the crack is extended. I — the intact area.

For the energy release rate, the previous equation becomes, [52];

$$\Delta G = \frac{\Delta E}{\Delta A} = \frac{1}{2} \mathbf{F} \frac{\delta_u - \delta_l}{\Delta A} \quad (2)$$

where ΔG is the total energy release rate, ΔA is the crack surface created and \mathbf{F} is the force to close the crack, δ_u is the displacement for the upper node and δ_l is the displacement for the lower node. Therefore, just by comparing the energy release rate with the critical value, the crack would propagate accordingly.

The self-similar crack growth requirement spawns complicated *remeshing algorithms* in order to keep the mesh in the crack tip to be able to move in the available directions [24,64]. Moreover, the mesh in the VCCT region should be very refined to reach accurate results [9]. However, today, VCCT become more advanced, thus, it would be better to mention additional features that have been recently embedded into VCCT in order to deal with the complex remeshing requirement [33-34,67] and cumbersome mesh size restrictions [9,35].

Xie et al. [33-34] proposed a front tracing method to deal with the self-similar crack growth limitation of VCCT. The proposed way of amendment is performed by defining the crack propagation with the help of displacement vectors. This front tracing method provides the capability of using relatively simple, stationary mesh patterns to simulate the moving delamination having an arbitrary shape without adapting the mesh as the delamination shape changes. However, since the mesh is not updated, the crack movement is in “zig-zag” behavior which gives oscillatory energy release rate results. Therefore, these results in rather high discrepancies around the analytical solution, hence the accuracy is not well.

The second modification for the VCCT was suggested by Orifici et al. [67] who proposed a method based on the *Multi-Point Constraint* (MPC) technique. The method proposes using predefined crack growth patterns with the addition of a *modifying factor* that is used for scaling the calculated energy release rate by FEM. This ingredient factor is taken into account between the calculation processes of the strain energy release rate and following the MPC release whether, for each failing MPC, the energy released in crack growth would correspond to that value or not. However, the method of Orifici et al. [67] offer a certainly less conservative approach for handling the crack growth propagation if one compares the results [67]. Even further, the relationships between the local crack front shape and the energy released in crack growth determined for the specimen in [67] may not be applicable to all other types of structures and all other types of crack growth patterns.

As another amendment for VCCT, Beuth [9] has proposed a means of extracting energy release rate components at interfaces where there is an oscillatory singularity. Yet, in this approach, the stress intensity factors are normalized to a distance that is typically chosen to be between $h/4$ and h , where h is the ply thickness. In Beuth's study, energy release rate components are obtained by typical VCCT, however the only difference is that they depend upon the normalizing length. The advantage in the approach is that it can be used with any reasonable level of mesh refinement to determine how the mode mix will change with different finite amounts of crack closure. Therefore, it "softens" the strict requirement of mesh sizes in a typical VCCT approach. Unfortunately, the disadvantage of Beuth's approach is that it cannot be used if the plies bounding the delamination do not have their principal axes aligned with the direction of crack growth. Unfortunately, Beuth's approach is not able to be applied in all of the engineering problems.

The last amendment for the mesh size restriction of VCCT is the θ - *method* which was first developed by Destuynder et al. [35]. The method takes its name after the vector describing the delamination front displacement field θ . The criterion is nothing but the weak variation form of the classical Griffith's criterion. Actually, the method has similar methodology like VCCT in terms of finite element analysis. Yet, it does not require highly fined meshes being required by the original VCCT. However, the method still need remeshing schemes since the crack front issue is still problematic.

In summary, although there are awesome studies for dealing with the mesh size requirements and the self similar crack growth, they could not be applied to all engineering applications or would not show accurate results.

2.3.2.1 VCCT vs. CZM

VCCT method has some awesome features that are mainly based on ease of use. Yet, the inherent deficiencies like self-similar crack growth, initial crack requirements and oscillatory nature of the crack tip stress field makes VCCT method rather limited. On the contrary, CZM method is “free” of those limitations.

The most effective feature of VCCT method is ease of implementation into finite element solvers. The incremental displacements and the nodal forces are required inputs that are similar to CZM modeling. However, implantation of a constitutive relation is not a case for VCCT method that has only criterion of total energy release rate which can be easily calculated by nodal forces and displacements [86]. Hence, unlike the process seen in CZM method, VCCT can be quite easily implemented inside FEM codes. For instance, VCCT does not require any user defined interface elements which is an unavoidable agent in CZM.

In addition, VCCT is so popular that the method is now inherently available inside most of commercial finite element packages like ABAQUS, MSC.NASTRAN and MSC.MARC [24,64]. Following the high availability, VCCT has already been started to be used in engineering applications like for delaminations originating from matrix cracks in skin-stringer interfaces when subjected to arbitrary load conditions [53,56].

However, VCCT has such severe limitations that they inhibit to be used efficiently in many engineering applications. First problem is the “oscillatory nature” of the singular crack-tip stress field. It introduces numerical instabilities during the numerical solution scheme as well as mesh-dependence in the numerical results [105]. Likewise, Raju et al. [74] showed that individual components of the energy release rate cannot converge when the ratio of the size of delamination tip element to the ply thickness decreases. In order to deal with the numerical instabilities in VCCT, the mesh sizes are defined by restrictive rules for element size in the crack-tip zone which has to be between $\frac{1}{4}$ and $\frac{1}{2}$ of the ply thickness. Therefore, VCCT approach can only be computationally effective when sufficiently refined meshes are used.

The limitation of mesh size for VCCT is analogous to limitation of CZM. According to Turon et al. [96], the number of elements at the cohesive zone should be at least three in order to obtain converged solutions. By this restriction and the one presented previously for VCCT, one could compare VCCT and CZM mesh size requirements in the simulation of DCB test. To do that, a DCB test simulation from [96] could be taken as a reference. The DCB is 150 mm in total length, 55 mm in crack length, 20 mm width and 1.98 mm thickness of two arms and a ply thickness is 0.165 mm.

In this model, Turon et al. found out that interface element size below 0.5 mm is adequate to have good convergence performance for CZM method when the cohesive zone length is about 0.95 mm. On the other hand, for the convergence requirement of the VCCT, recall that $\frac{1}{4}$ and $\frac{1}{2}$ of the ply thickness yields element sizes between 0.08250 mm to 0.04125 mm. The resulting meshes for each of VCCT and CZM methods are illustrated in Figure 10.

Figure 10: Mesh sizes for the DCB model for (a) CZM (b) VCCT methods.

As seen in Figure 10, the representing mesh resulting for VCCT is much finer than the mesh required for CZM. One could claim that VCCT needs finer meshes only in the crack front, whereas, CZM requires fine mesh throughout the interface. However, the crack front should be traced by the mesh as it propagates in VCCT; therefore, this makes the meshes in VCCT quite fine throughout the whole propagation. Therefore, such a comparison could be applicable.

As explained in the amendments for VCCT, there are various studies for dealing with the fine mesh requirement, which are θ -method [35], and the Beuth's method [9]. Yet, these are not so powerful

tools to overcome fine mesh requirement easily because of their deficiencies explained in the preceding paragraphs.

To be an additional handicap of VCCT method, there should be an initial crack; otherwise, FM does not work. On the other hand, the location of the delamination crack front might be difficult to be determined for certain geometries and load cases [105]. Therefore, sometimes, it is not so easy to put a crack to start an analysis. Whereas, since the damage mechanics is able to determine the onset of delamination by using strength of material approach, CZM method does not involve such a requirement.

In addition, a crack is able to grow in a self-similar fashion, such that, the crack front must maintain the same shape as the crack propagates in VCCT [33,55,67]. In engineering applications, the requirement of self similar crack growth is a considerable handicap for delamination growth simulations. VCCT has been limited in this respect due to the requirement of fine mesh modeling in the order of ply thicknesses and the need for complicated algorithms to monitor the shape of the crack front. Typically, this problem is overcome by complicated re-meshing algorithms that successively re-mesh the crack front to catch the new front accurately [55]. Orifici et al. [67] and Xie et al. [33-34] have developed some methods that are already mentioned in preceding paragraphs to cope with this limitation. However, these solutions are not versatile or not giving adequately good results as mentioned. In addition, the strict requirement of non-variable state of crack front prevents VCCT from being used for several classes of very important delamination problems, including free edge crack nucleation and propagation, and delamination in a composite panel due to low-velocity impact [105]. On the contrary, CZM method was already applied successfully for low velocity impact resulting a delamination on the edge [31,45] where the resulting mesh is propagating in a non-self-similar manner as shown in Figure 11.

Figure 11: Initial delamination due to low velocity impact and predicted delamination propagation used by CZM in a compressive loading [31].

A feature of the cohesive method could be stated as a final distinguishing property, which is *damage parameter*. Actually, VCCT method can only define the laminate is whether failed or not; just like “black” or “white”. On the other hand, CZM method could define the state of delamination over the damage parameter. For instance, the simulation of the delamination due to the low velocity impact damage, Batra et al. [45] showed that the damage levels of the crack region is varying as a function of time as shown Figure 12. One can easily distinguish the regions where the matrix cracking is emerging, and where the total debonding is occurred. Therefore, even after unloading, intact and damaged regions can be distinguished.

Figure 12: Fringe plots with the damage parameter evolution [45].

As a summary, although the VCCT method is simpler than the CZM method, the CZM method is more capable and versatile and even more conservative.

2.3.3 Other Delamination Analysis Methods

In addition to typical FM method and CZM, there are unique and distinguished studies used for the delamination propagation.

One such proposal is from de Borst [29] and Remmers et al. [78] who offered to bring out the ability of non similar crack growth for the whole structure. As noticed from Figure 13, the crack can move in any direction without needing any interface element. In other words, the crack is able to move “inside” the elements, which are used for modeling the intact structure. As a result, a powerful method has been developed to fully exploit the potential of cohesive-zone models for the arbitrary crack propagation. Actually, this procedure is referred with a special name called “XFEM” in the commercial FEA packages [24,64]. The modification here is performed inside the element formulation of which the details can be found in [29].

Figure 13: Arbitrary crack propagation is allowed to move inside elements [29].

Another study seeking a remedy for the restriction of propagating in all directions, Wells et al. [100] proposed a unique solution. They resemble a key feature in that the material structure and the finite element mesh are uncoupled. Therefore, hexagonal or non planar elements can be used for the delamination analysis as shown in Figure 14.

Figure 14: Uncoupled material and mesh feature resembling non-planar delamination surfaces [100].

2.4 Failure Modes

When a composite structure is remotely loaded, the resolved stresses are *interlaminar tension* and *interlaminar shear* stresses at the discontinuities in mixed-mode or pure modes of mode I, mode II and mode III [55]. The fracture modes; the *interlaminar tension* (Mode I), *interlaminar shear* (Mode II) and *interlaminar scissoring* (Mode III) modes as can be seen in Figure 15.

Figure 15: Fracture modes

The element formulation developed in our study is capable of dealing with mixed-mode failure modes. Since the mixed-mode possesses individual pure modes, the pure modes and the mixed-mode failures, together, are discussed briefly in this section. However, since the benchmark test model is DCB specimen, analytical approximate formulations for Mode I is given.

2.4.1 Mode I Fracture Mode

The opening mode of laminates is related to Mode I failure (Figure 15). The test that defines the critical Mode I energy release rate is *Double Cantilever Beam* (DCB) test which is also modeled in our study. The specimen is made of a unidirectional fiber-reinforced laminate containing a thin insert at the mid-plane near the loaded end (Figure 16). The definitions and the details like dimensions and loading are standardized and one can be found them in [7].

Figure 16: Schematic illustration of DCB test.

There are some problems for acquiring the accurate results from the DCB test with laminated composites. The major problem associated with the test is the phenomenon of *fiber bridging* across the crack as it moves above and below bundles of fibers as shown in Figure 17.

Figure 17: Fiber bridging during DCB test [70].

It should be noted that such details are typical characteristic responses of the DCB test, that affect directly the *R-curve* as instanced in Figure 18 [13]. One can realize from the below figure that there are two distinct *critical energy release rates* (or *fracture toughness*, G_{Ic}); one for initiation and one for propagation.

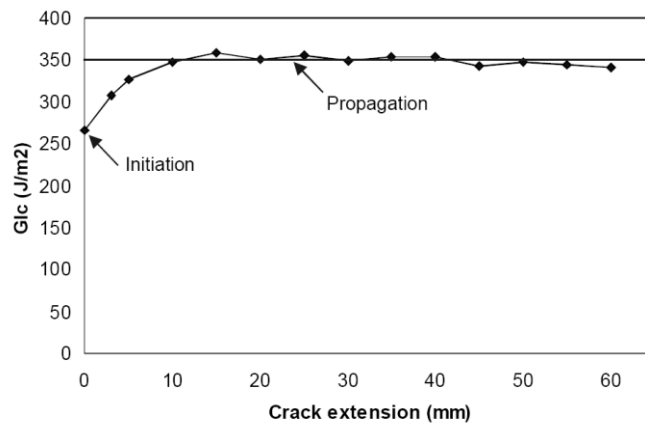

Figure 18: R-curve effect on a DCB test of a (0°)₂₄ CFRP laminate [13]

Although DCB test specimens are unidirectional (0°) laminates, it would be convenient to obtain interlaminar fracture toughness for interfaces between other than 0° plies. Fortunately, it has been shown that unidirectional composites provide the most conservative values for G_{Ic} , such that, higher values of G_{Ic} are obtained for interfaces other than 0°/0° stacking, [13]. Also, a DCB test using arms with unequal bending stiffness will also promote Mode II loading, [13] A modified DCB specimen and a new test method designed to overcome these problems, was proposed by Robinson and Song [84]. Preliminary tests [84] have also resulted in significantly higher values of G_{Ic} for

multidirectional laminates compared with unidirectional laminates. It is crucial to note that CZM methodology is same for the multi-directional composites, providing the crack interface surfaces are in same orientations.

At the crack tip in DCB specimen, the energy release rate across the width decreases closer to the edges, as shown in Figure 19. One can realize that the plane strain solution is the one at the middle with a constant value from Figure 19. Actually, such effect seen is due to the *anticlastic deformation* [90] which is a three dimensional phenomenon which can be seen only in 3D applications; not in plane strain problems. Therefore, the anticlastic effect would make the inner sections delaminated earlier. Figure 19 is directly used for comparing the current energy release rate with the fracture toughness.

Figure 19: Strain energy release rate across width of DCB specimen at the crack front [90].

The resulting effect for CZM is variation in the *process zone* where the *softening* is being shaped as shown in Figure 20.

Figure 20: Evaluation of process zone at crack tip in a DCB test due to anticlastic effects [59].

Although CZM is summarized mainly by means of physical issues, finite element modeling of DCB test in our study is checked with the analytical approximations. To start the analytical solution, one can consider one of the arms as a cantilever beam in which the length of initial crack length a_0 as shown in Figure 21.

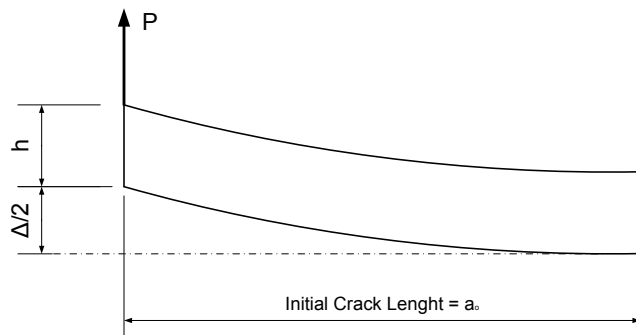

Figure 21: One of arms is treated as cantilever beam.

From fundamental elastic beam theory, one can find the deflection of the cantilever beam applicable for a DCB arm;

$$\frac{\Delta}{2} = \frac{Pa_0^3}{3EI} \quad (3)$$

Actually, modulus (E) in the above equation is the modulus works “along” the beam, therefore, $E = E_{11}$. Moreover, inertia (I) is for simple rectangular cross-section; $Bh^3/12$ where B is the width and h is the thickness of the arm.

In reality, the clamped surface is being “rotated” during the loading due to the shear deformation of the assumed “clamped” elastic arm. As a result, the fixed clamped arm assumption would result in “stiffer” results than the real case [77]. Consequently, a “corrected beam theory” is proposed by Williams et al. [44] who modified the crack length with a *correction parameter*, χ_I (Noting the subscript “ I ” which is used here is for defining the mode of the correction factor).

$$\Delta_i = \frac{2P(a_0 + \chi_I h)^3}{3E_{11}I} \quad (4)$$

where, the correction parameter, χ_I can be found both by experimentally or analytically [43]. Our study takes the analytical solution as follows [44];

$$\chi_I = \sqrt{\frac{E_{11}}{11G_{13}} \left[3 - 2 \left(\frac{\Gamma}{1 + \Gamma} \right)^2 \right]} \quad (5)$$

where

$$\Gamma = 1.18 \frac{\sqrt{E_{11}E_{22}}}{G_{13}}$$

One can observe that the relation between tip load P and tip displacement Δ is linear. Actually, as the load P increases, the displacement increases linearly.

From the damage mechanics literature, the load can be increased until the cohesive element started to soften. Until the energy release rate G_I reaches the mode I critical energy release rate, G_{Ic} . Therefore, the energy release rate is defined as [77];

$$G_I = \frac{P^2(a + \chi_I h)^2}{BE_{11}I} \quad (6)$$

Noting that, the initial crack length a_0 in Eqn. (6) is replaced by the current crack length “ a ” due to the reason that the crack start to vary. As a result, since the “modified” cantilever beam theory and the energy release rate definition holds throughout the delamination, one can combine Eqns. (5) and (6) to obtain a unified solution. Since the delamination starts to propagate when $G_I = G_{Ic}$, the unified solution curve after the failure can be written as [77];

$$\Delta_f = \frac{2(BE_{11}IG_{Ic})^{3/2}}{3E_{11}IP^2} \quad (7)$$

By putting the initial crack length a_0 and critical energy release rate G_{Ic} inside the Eqn. (6), the tip force at the crack growth regime becomes;

$$P_c = \frac{\sqrt{G_{Ic}BE_{11}I}}{a_0 + \chi_I h} \quad (8)$$

Following that, one can easily find the critical tip displacement at the crack growth just by putting the P_c inside one of the displacement equations above. As a result, the typical response is illustrated in Figure 22.

Figure 22: Approximate analytical solution for DCB.

2.4.2 Mode II Fracture Mode

Unlike Mode I, there are four distinct types of test for acquiring Mode II fracture toughness, G_{IIc} . These are *(Three Point) End Notched Flexure (ENF)*, *Stabilized End Notched Flexure (SENF)*, *Four Point End Notched Flexure (4ENF)*, and *End Loaded Split (ELS)* tests [27]. Although ENF test specimen has received the most attention, it has problems associated with unstable crack propagation for short crack lengths [27]. In fact, the uncertainties are more typical for all of the mode II tests, that is why; there are many tests suggested with each having a defiance.

The main problems associated with Mode II test are the definition of the type of starter defect, the definition of crack initiation, the stability of the test, frictional effects on the crack faces and the data analysis [27]. Actually, since the contact maintained between the delaminated surfaces during the test, mode II has friction effect throughout the crack [105]. As a reference, the fracture toughness of Mode II is typically much higher than the one for Mode I. For instance, epoxy matrix composites the G_{IIc}/G_{Ic} ratios typically exceed 2 [27].

2.4.3 Mode III Fracture Mode

The delamination can be defined totally only if all subsequent modes are defined. Actually, as to be seen in the following sections, the main concern for defining the mode test is to obtain the mixed-mode response of the specimen.

The impact of mode III on delamination is controversial [105]. Just a few studies exist on mode III failure. According to Donaldson [105], numerical results reveal that the delamination near a notch is totally driven by mode III. Whereas, Krueger [53] experimentally showed that the effect of Mode III can be neglected. In our study, since the assumption is *plane strain*, the mode III effect is automatically neglected.

There is a candidate testing method for Mode III called *Edge Crack Torsion (ECT) test* suggested by Lee [58]. However, the parameter required for the test -the shear modulus G_{23} - needs full clarification due to the way to be determined [12]. As a result, ECT has not been standardized yet.

2.4.4 Mixed-Mode Fracture

The engineering applications are generally in mixed-mode condition where the loading would not always be in pure modes. Therefore, the two key points of *delamination initiation* and *delamination propagation* should be investigated. More importantly, the formulations mentioned in this section are used in the element formulation in our study.

2.4.4.1 Initiation

One of the most widely used criteria for initiation is proposed by Ye [106]. The proposal involves the pure mode allowable stresses in an interaction that resembles an *elliptical behavior*. Hence, the formulation is written as follows [106];

$$\left(\frac{\langle t_{III} \rangle}{t_{IIIc}} \right)^2 + \left(\frac{t_{II}}{t_{IIc}} \right)^2 + \left(\frac{t_I}{t_{Ic}} \right)^2 = 1 \quad (9)$$

where the t_{Ic} , t_{IIc} and t_{IIIc} are mode I, mode II and mode III interfacial strengths of the interface. Similarly, the t_I , t_{II} and t_{III} are mode I, mode II and mode III interfacial tractions. Note that the operator $\langle \cdot \rangle$ is called *Mc-Cauley* operator which can be defined as;

$$\langle x \rangle = \frac{x + |x|}{2} \quad (10)$$

This criterion is called *quadratic (or elliptical) criterion* that is shown in the Figure 3 with other criteria. Our study uses this criterion for the delamination onset in order to take into account the onset of delamination.

2.4.4.2 Propagation

To account for the mixed-mode effect, Reeder and Crews [77] suggested the test of *mixed-mode bending* (MMB) which is widely in CZM studies [1,13,16,54,59,71-72] used successfully.

Figure 23: Mixed-Mode Bending (MMB) test [70].

The way for finding the appropriate equations for the MMB test is straightforward. Up to the crack growth, the MMB is nothing but a superposition of DCB and ENF testing. Therefore, from the definitions of DCB and ENF, the resulting forces are statically determinate as being formulated in Figure 24.

Figure 24: DCB and ENF test correlation by superposition feature of MMB (not scaled).

In order to define the amount of the mixture of the pure modes, a ratio should be required. *Total energy release rate* G_T , the summation of the pure mode energy release rates, is used inside the definition of the ratio called *mixed mode ratio* β can be defined as;

$$\beta = \frac{G_{II}}{G_T} = \frac{G_{II}}{G_I + G_{II} + G_{III}} \quad (11)$$

A typical result of mixed mode interaction for an epoxy matrix carbon fiber composite is shown in Figure 25. The first point in the curve is $G_{II}/G_T = 0$, showing that the only contribution is by mode I. Therefore, DCB test can be used to locate this point. Conversely, there is pure mode II if the $G_{II}/G_T = 1$; hence, ENF test is adequate. On the other hand, successive MMB tests are required for finding the mid-points. So as to cover the curve, different G_{II}/G_T is selected and tested by MMB. An example for a typical result is illustrated in Figure 25 for an epoxy/graphite composite.

Figure 25: Mixed-Mode and mode I, II failure criteria for an epoxy/graphite composite [95].

Benzeggah and Kenane [9] suggested a failure criterion by curve fitting for G_c vs β curve (Figure 25) as follows;

$$G_c = G_{Ic} + (G_{IIc} - G_{Ic})\left(\frac{G_{II}}{G_T}\right)^\eta \quad (12)$$

where the factor η is found by curve fitting. Benzeggah and Kenane (BK) criterion is taken as a failure criterion for CZM analysis successfully; for instance, by Unified Mode Approach [13,105].

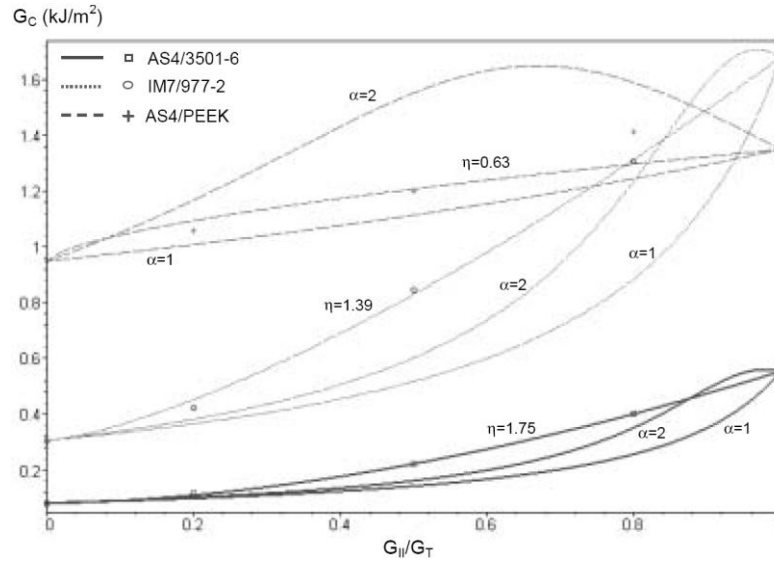

Figure 26: Factor of η in Benzeggah and Kenane criterion, α for power law criterion and corresponding fracture toughness values for various composites [12].

Nevertheless, Eqn. (12) cannot be applied easily for all engineering applications, because of the requirement for experimental data to find the factor η . Therefore, a more robust failure criterion was suggested and used effectively, which is called *power law* [2,59,72];

$$\left(\frac{G_I}{G_{Ic}}\right)^\alpha + \left(\frac{G_{II}}{G_{IIc}}\right)^\alpha = 1 \quad (13)$$

where for most of the carbon/epoxy composites, the mixed-mode data can be accurately represented using $1 \leq \alpha \leq 2$ [15,71]. For instance, PEEK matrix composites are best fitted with $\alpha = 1$ [12]. It should be noted here that Separated Mode Approach uses power law criterion since the failure criterion is represented only by pure mode energy release rate values.

One may remark that the above mixed-mode propagation criteria do not involve G_{IIIc} . This is due to the facts that are mentioned in the mode III section. Consequently, it is generally suggested to use propagation equations by replacing G_{II} terms with *shear energy release rate* definition such that $G_{shear} = G_{II} + G_{III}$ [12]. Since our analysis is two dimensional with plane strain assumption, there is no Mode III energy release rate; therefore, this automatically yields; $G_{shear} = G_{II}$.

Finally, to show the whole picture, the tip load vs. displacement curves and the corresponding critical loads for delamination crack propagation can be compared from Figure 27.

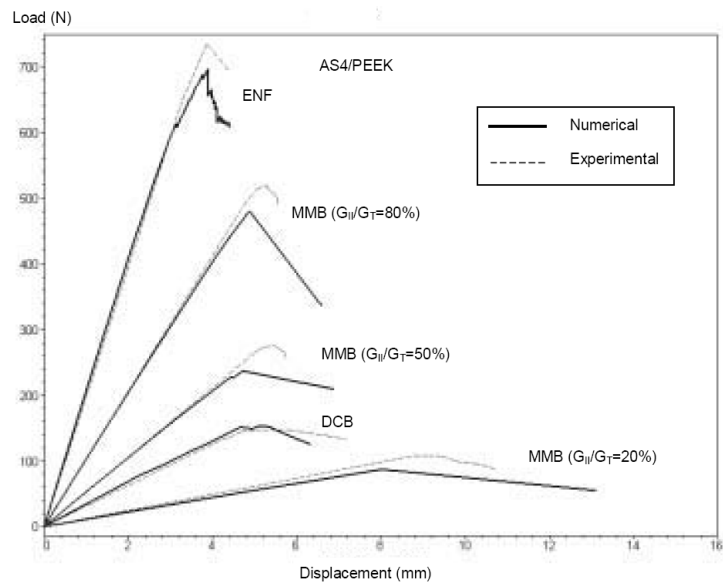

Figure 27: Various mode tests for AS4/PEEK carbon fiber unidirectional composite [12]

CHAPTER 3

COHESIVE ZONE METHOD DELAMINATION ANALYSIS

3.1 Cohesive Zone Model

The cohesive zone approach can be explained on a detail view of the crack tip. The crack has a *process zone* acting as a transition region between traction free and the linear elastic region of the bulk material [8]. This region has a different non-linear profile; named by Barenblatt [8] as *outer region* whereas the traction free part it is named as *inner region*.

The physical phenomena behind the process zone was first proposed for concrete materials as *bridging* due to second phase particles and away from bridging, *micro-cracking* were responsible [48]. This can be characterized as *micro structural linkage units* may be identified with cohesive bond in brittle solids, *ductile filaments* in plastic solids, *transverse molecular chains* in polymers [5]. For composites, however, *load-bearing fibers*, *voiding* and *crazing* are the physical phenomena resulting in such a process zone [5].

Figure 28: (a) Bonding and de-bonding actions for the process zone (b) Top view of inner and outer regions

In Figure 28a, it can be realized that the process zone is illustrated by set of “springs” so as to imply the existence of *cohesive forces* which result in a unique traction profile at the crack edge. Also, the edge of the crack is drawn like sharp tip of a water drop to reveal that the cohesive effect is dominant in the *cohesive zone* only. In fact, the springs are considered as a continuum of cohesive forces in *Continuum Cohesive Zone Method (CCZM)* whereas they are discretely taken into account in *Discrete Cohesive Zone Method (DCZM)*, pioneered by Xie and Waas [32]. The theory behind both approaches are identical, just the methodology in element modeling is different. However, both cases are valid, only if the process zone is much smaller than the crack [6,8]. In our study, the most generally used method; Continuum Cohesive Zone Method is used because of the interface element type selected.

The application of the cohesive zone method is directly based on which of the cohesive models being used. CZM relates tractions to displacement jumps at an interface where a crack may occur [42]. In other words, the models contribute *traction (or stress)-displacement* profiles dealing with specific materials and interfaces. The first cohesive stress model suggested by Dugdale [36] was using constant stress profile for dealing with plastic materials as shown in Figure 29a. However, the proposal gives *full plastic* behavior which could not yield correct results for composite materials.

The most frequently and successfully used model is the one called *bilinear model* proposed by Mi et al. [59] (Figure 29b). The bilinear model gives accurate results for composite materials and that is why this model is used in our study.

Figure 29: (a) Dugdale model [36] in cohesive zone (b) Cohesive zone stress distribution by Mi et al. [59].

The application of cohesive model is performed by finite element analysis in which the candidate delamination surfaces are modeled by *interface elements* (Figure 30) obeying cohesive zone constitutive relationship. As understood from the name “interface”, the elements are located between the adjacent plies where the delamination occurs.

Figure 30: FE model and 3D interface elements in a DCB test specimen [43].

In fact, the interface elements are supposed to be in zero or near-to-zero thicknesses because they are located in the interfaces without affecting the real thickness, or simply the whole part. Otherwise, the interface element can increase the actual thickness of the specimen; hence, the global response can be incorrect. This is the reason why the constitutive relations depend on displacements, not strains. Otherwise, one can come up with extremely sensitive strains which may result in numerical instabilities for FE solvers. Moreover, as can be seen in the following paragraphs, FE solver would give *aspect ratio* errors [61] because of the element height over element width ratio become near to zero.

The displacements in CZM are *relative displacements*; δ , as shown in Figure 31 in which the two surfaces represent the adjacent delamination surfaces. In other words, the lower and upper surfaces are adjacent laminae in our study. The relative displacement is between the “top” and the “bottom” surfaces in the interface continuum. Later on, this definition will be presented in more detail.

Figure 31: Cohesive element relative displacement definition and separation of the surfaces.

After the above fundamental definitions, it is better to return to cohesive zone models and corresponding constitutive relationships. A typical constitutive relationship for composite delamination analysis is the one used in the pioneering work of Needleman [66] shown in Figure 32. Recalling that, there are pure modes (Mode I, Mode II, and Mode III) being related to the engineering problems. Thus, the normal traction versus opening displacement curve shown in Figure 32a is the Mode I response, whereas, the shear traction versus tangential displacement curve shown in Figure 32b, is the Mode II or Mode III.

Figure 32: Needleman's traction-displacement constitutive model, [66] (a) for Mode I and (b) for Mode II (or Mode III).

It can be easily seen from Figure 32 that the shear and opening mode responses have a similar behavior, yet with a different behavior at negative displacement. For mode I, any negative relative displacement corresponds to interpenetration of delamination surfaces which cannot be allowed [72]. Therefore, quite a stiff resistance would emerge for preventing the interpenetration of the delamination surfaces. On the other hand, for Mode II and Mode III, the negative relative displacement is nothing but a directional situation for the deformation. Consequently, whether the displacement is negative or not, the response of the cohesion zone would be the same.

In addition to Needleman's study, there are various constitutive formulations proposed for delamination analysis; linear elastic, linear softening, linear elastic-progressive softening and linear elastic-regressive softening [27] as summarized in Figure 33.

Figure 33: Various traction-displacement interface constitutive relations [27]

From Figure 33, it can be revealed that all of the constitutive relations have similar behaviors. This is due to the fact that the interface elements behave in three unique regions; [1,13,16,59,95-96];

- *Intact region,*
- *Softening region,*
- *Failed region.*

They are all shown in Figure 34, illustrating on the bilinear relationship.

Figure 34: Characteristics of constitutive relations (bilinear relationship).

Intact region is dedicated for the ideal bulk material representation, that is, the undamaged part. The intact region goes up to the point (δ_o, t_c) where *delamination onset* occurs. This is the point where chemical bonds of the intact materials start to be broken, in other words, the cohesive phenomenon starts. Therefore, the maximum traction t_c is the interfacial strength defining the onset.

There remains only the delamination onset δ_o which is not related to any phenomenon. Actually, this parameter has nothing to do with CZM. The implantation of the method yields non-zero delamination onset displacement does, because of the requirement of initial tangent stiffness matrix. The slope of the curve in intact region is called *penalty stiffness*, E_0 being selected as high as possible for giving accurate results while avoiding excessive values causing convergence problems [96]. More specifically, using high penalty stiffness would result in high stresses in accordance with the singularity which is found in the traction profile at a sharp crack tip in a LEFM model for having a sufficiently accurate pre-crack behavior [72]. As going to be discussed in our study, this parameter is very important for CZM.

After delamination onset, the softening of the interface occurs due to the cohesive effects like fiber bridging, crazing and microvoiding [13,105], which are pointing the phenomenon of cohesive effects. *Softening region* is the one between delamination onset displacement δ_o and the critical displacement relating to the total failure, δ_c in term of the constitutive relationship. Moreover, the softening region is the problematic phase responsible for the sharp-snap backs that would yield convergence problems, [2,59].

The requirement for a softening region emerges due to *damage mechanics* approach being used for deriving the constitutive behaviors [1,95]. The details of damage mechanics derivation shall not be given here, since it is discussed extensively in [1,95]. Yet, damage mechanics derivation results in the traction versus displacement profile that is given as follows [1];

$$t = (1 - d)E_0\delta \quad (14)$$

where the “ d ” is the *damage* term to be defined analytically in the next chapter. One can understand from Eqn. (14) that the line equation of “ $(1 - d)E_0$ ” shows a declining behavior as the damage term increases from no damage value of 0 to fully damaged value of 1. This reveals a theoretical cohesive zone as shown in Figure 35.

Figure 35: Theoretical cohesive zone constitutive relationship with “infinite” penalty stiffness.

For the last phase, when the critical displacement, δ_c exceeded (or damage is fully attained with $d=1$), *full delamination* happens; or in words the interface element is *fully failed*. After this point, the cohesive elements would behave as a traction free crack. It should be noticed that, the existing phenomenon other than cohesive forces like interpenetration prevention for Mode I or frictional effects for Mode II and Mode III are still active. Actually, this feature has nothing to do with cohesive methodology; however, it is used for the sake of modeling “real” interfaces.

3.1.1 Definition of Cohesive Zone Length

The boundary of cohesive zone was implied in the previous paragraphs as the distance from the maximum attained traction to the zero traction. It is shown as L , defining the cohesive zone as the detailed view given on a DCB specimen in Figure 36. Hence, the region bounded by the points 2 to 4 defines the softening of the interface; the cohesive zone.

Figure 36: Cohesive zone in the vicinity of crack and bi-linear constitutive relationship. (Not to scale)

Actually, the size of cohesive zone is referred as *cohesive zone length* in literature. The word “length” is used since the thickness of the zone is quite small and therefore it can be neglected. Turon et al. [96] studied the length of cohesive zone extensively. It is pointed that [96] there are many analytical cohesive zone length approximations variable from specimen to specimen. It is also stated that the main characteristics of all proposed length approximations have the same structure that is given as [96];

$$l_{cz} = (M)E_{22} \frac{G_c}{(t_c)^2} \quad (15)$$

Where different M values are given in Table 1;

Table 1: Different M values for plane stress approximation in literature [96]

<i>Proposed by;</i>	M
Hui et al.	0.21
Irwin	0.31
Dugdale and Barenblatt	0.40
Rice, Falk et al.	0.88
Hillerborg et al.	1.00

Remaking, the above length approximations are for *plane stress* condition; unlikely used for our study. Also, the original version of Eqn. (15) uses isotropic modulus (E) instead of transverse

modulus; (i.e; $E_{22} = E$). Note that, Turon et al. [96] obtained best results with the approximation of Rice. This result is going to be checked in our analysis also although it is for plane stress.

On the other hand, Harper and Hallet [43] once remarked that the theoretical cohesive zone length formulations in literature and the one obtained by FEM are different. Therefore, the exact matching for the above formulations with FEM results cannot be met.

The cohesive zone length is directly related to the convergence issue that is the most crucial point for the CZM applications. The most predominant convergence effective criterion is the mesh density in the cohesive zone [15-16,71-72,96]. Turon et al. [96] suggested that the minimum number of elements required for reaching converged solutions should be more than two elements. Therefore, the resulting element length can be given as;

$$l_e \leq \frac{l_{cz}}{3} \quad (16)$$

Where l_e is the length of individual interface element located inside the cohesive zone. As a note here, there is a trick usually performed by the researchers, and also done in some cases in our study. It is to increase the cohesive zone length so as to benefit convergence rate [2]. Actually, the trick is activated by artificially lowering interfacial strength in Eqn. (15), that increases the cohesive zone length, and at the same time the number of interface elements staying inside the zone. However, this artificial modification would not yield accurate results if the interfacial strength was decreased excessively [43]. This phenomenon is also revisited in our bench mark test model.

As a summary, the whole process of damage advancement can be illustrated in Figure 37. It can be seen that, there are two elements initially representing the cohesive zone. When the critical tip displacement attained, the cohesive zone is “hatched” and started to get expand to the right. One may reveal that some elements may reach to the maximum traction (t_c) and start to be softened, before the maximum tip force is attained. Actually, the point, where the maximum tip load attained, is the location where a mature cohesive zone formed.

Figure 37: Cohesive zone evolution as tip load increases for a DCB test model [43].
(LCZ: The Cohesive Zone Length)

3.1.2 Griffith's Theory in CZM

Although the original derivation should be the damage mechanics, the cohesive zone formulation is also identical to Griffith's theory of fracture [40]. It should be noticed that the use of Griffith's theory is not fully correct in terms of the assumptions it requires. However, for the sake of simplicity and the equivalence of the resulting equations, Griffith's theory is used in our study to finalize the CZM formulation.

Now, if one considers the J-integral proposed by Rice on the boundary Γ [80];

$$J = \int_{\Gamma} (w dy - t \frac{\partial u}{\partial x} ds) \quad (17)$$

where Γ is any contour surrounding the notch tip, \mathbf{u} is the displacement vector, \mathbf{t} is the traction vector defined accordingly to the outward normal along Γ , and w is the strain energy density. From the constitutive relation shown in Figure 36;

$$J = \int_{\Gamma} (w dy - \sigma(\delta) \frac{\partial \delta}{\partial x} dx) \quad (18)$$

By neglecting the thickness of the cohesive zone, it can be taken into account that $dy = 0$ for the selected integral path;

$$J = - \int_{\Gamma} (\sigma(\delta) \frac{\partial \delta}{\partial x} dx) = - \int \frac{d}{dx} \left(\int^{\delta} \sigma(\delta) d\delta \right) dx = \int^{\delta} \sigma(\delta) d\delta \quad (19)$$

Under the assumptions of *self similar crack growth* and *small cohesive zone* comparing with the crack length, one may use the energy release rate definition as, [80];

$$J = - \frac{\partial \Pi}{\partial a} = G \quad (20)$$

Therefore, from Eqn.(19) and Eqn. (20);

$$G = \int^{\delta} \sigma(\delta) d\delta \quad (21)$$

Considering the final crack displacement of the critical displacement, δ_c ;

$$G_c = \int^{\delta_c} \sigma(\delta) d\delta \quad (22)$$

Meaning that the area under the constitutive relationship is equal to the critical energy release rate, G_c . As a result, since the remaining unknown parameter, the *critical displacement*, δ_c is found, the whole bilinear constitutive relation is now attainable.

3.2 Mixed-Mode Cohesive Zone Model Derivation

Up to now, we considered the pure mode constitutive behaviors and their fundamentals. However, the response of delamination would not be straightforward in the mixed-mode loading. Just like in the critical energy release rate, a study for the mixed-mode cohesive constitutive relationship is compulsory. Notably, although there would be no benchmark test like MMB in our study, the elements would have full capability for dealing with mixed-mode loading, and therefore, the mixed-mode formulations are going to be derived.

Now, consider a 3D interface element shown in Figure 38. The total relative displacement vector δ can be defined in terms of local coordinate system $(1,2,3)$ displacements; δ_1 , δ_2 and δ_3 as;

$$\delta = \sqrt{\delta_1^2 + \delta_2^2 + \delta_3^2} \quad (23)$$

It can be seen that the subscript for opening displacement is taken with the character “1” whereas the numeric subscripts of 2 and 3 are used for the Mode II and Mode III, respectively. This is due to the fact that, the orthogonal displacement component corresponds to the opening mode I. On the other hand, the others are contributing the shearing displacement together as discussed before.

Figure 38: Pure mode displacements in an interface element.

Repeating here, Mode-III has very little effect; therefore, it is convenient to consider the displacements δ_2 and δ_3 as one as the shear mode. As a result, the contribution of Mode III is going to be neglected for the rest of this study.

The shear displacement δ_{shear} can be written as, [71],

$$\delta_{shear} = \sqrt{\delta_2^2 + \delta_3^2} \quad (24)$$

Then, Eqn. (23) becomes;

$$\delta = \sqrt{\delta_I^2 + \delta_{shear}^2}$$

Now, consider the opening mode and the shearing mode constitutive bilinear relations given in Figure 48;

Figure 39: Pure mode bilinear constitutive relationship.

For a mixed mode ratio of $\beta = 0$ the pure Mode I behavior on Figure 39a is adequate because the maximum interfacial strength and the critical energy release rate in Mode I is known from DCB tests. Similarly, for $\beta = 1$, the pure Mode II behavior on Figure 39b is adequate to proceed the analysis due to the Mode II test has already been specified. However, this is not the case for the mixed-mode, because the mixed-mode ratio varies as the loading advances. The failure criterion would be varying due to the interfacial strength is being changing due to quadratic criterion and the critical energy release rate is found by either the BK-criterion or power law. Finally, the resulting constitutive behavior should be the one shown in Figure 40.

Figure 40: Constitutive relationship for Mixed-Mode delamination

In Figure 40, it can be seen that there are superscripts “*M*” used for the mixed-mode extremities for the corresponding parameter in *pure mode planes*. Actually, there are two extremities; one for the pure modes and the other for the mixed mode. The reflections of the mixed mode ratio constitutive relation (the triangle at the middle) on the pure mode planes are to lower the maximum pure mode energy release rates (i.e.; $G_{Ic} > G_{Ic}^M$ and $G_{IIc} > G_{IIc}^M$) and the pure mode maximum of the tractions (i.e.; $t_{Ic} > t_{Ic}^M$ and $t_{IIc} > t_{IIc}^M$) and the displacements (i.e.; $\delta_{Ic} > \delta_{Ic}^M$ and $\delta_{IIc} > \delta_{IIc}^M$ similarly, $\delta_{Io} > \delta_{Io}^M$ and $\delta_{IIo} > \delta_{IIo}^M$). As a result, the all of the constituents for deriving the appropriate constitutive relationship can be performed by investigating Figure 40.

Many authors [16,27,43,59,71,96] pointed out that by maintaining the critical energy release rate, there would be no considerable difference among the all constitutive relationship results, even for artificially adjusting the interfacial strength for better convergence rates. On the other hand, Yang

and Cox [105] suggested using accurate constitutive relations for highly mixed-mode loading. Hence, the “rigidity” such a figure of Figure 40 is controversial.

3.2.1 CZM Constitutive Formulations for Mixed-Mode Failure

All of the approaches in literature start with fundamental formulations of the pure mode failures. In intact region, the penalty stiffness matrix generally has a pre-defined value avoiding numerical instabilities [96]; thus, the pure mode delamination onset displacement is the one found directly from the slope of the penalty stiffness as follows [1,12,71];

$$\delta_{io} = \frac{t_{ic}}{E0}, \quad i = I, II \quad (25)$$

The subscript “i” is addressing pure modes, and E0 is the penalty stiffness which is going to be distinguished for Mode I and Mode II by Separated Mode Approach [1]. On the other hand, for Unified Mode Approach [12], the penalty stiffness values for each pure mode are identical. Actually, the difference of the two starts from the definition for the penalty stiffness concept.

From the area of the triangle in Figure 34, the pure mode critical displacement can be found easily, [1,12,71];

$$\delta_{ic} = \frac{2G_{Ic}}{\delta_{io} E0}, \quad i = I, II \quad (26)$$

After that point, the pure constitutive relationship on mode planes of Figure 40 can be drawn. Afterwards, the mixed-mode approaches could be defined according to both formulations.

The basis for damage evolution is the total relative displacement, δ as suggested by Allix and Corigliano [3], Camanho et al. [12] and Pinho et al.[71]. Therefore, firstly by revisiting Eqn. (23), the interpenetration phenomenon in opening mode can be handled as follows;

$$\delta = \sqrt{\langle \delta_I \rangle^2 + \delta_2^2 + \delta_3^2} = \sqrt{\langle \delta_I \rangle^2 + \delta_{shear}^2} \quad (27)$$

where the δ_I is defined in Mc-Cauley brackets Eqn. (10) so as to remove any “closing” displacement from the total displacement parameter. As to be seen from the following paragraphs, the case for negative Mode I displacement is considered separately and named as *interpenetration*.

For mixed-mode ratio, β , Figure 40 shows that it is equal to the tangent θ ;

$$\tan(\theta) = \frac{\delta_{shear}}{\delta_I} = \beta \quad (28)$$

Referring to Figure 40, one may find the mixed-mode onset displacement by putting the onset displacement given in Eqn. (23) into the mixed-mode quadratic criterion in Eqn.(9);

$$\delta_0 = \begin{cases} \delta_{IIo} \delta_{Io} \sqrt{\frac{1 + \beta^2}{\delta_{IIo}^2 + (\beta \delta_{Io})^2}} & \Leftarrow \delta_I > 0 \\ \delta_{IIo} & \Leftarrow \delta_I \leq 0 \end{cases} \quad (29)$$

Remaking that, the negative displacement of Mode I is referring to interpenetration, where the mode I diminishes.

Now, from the angle of the mixed-mode, one can find δ_{io}^M and δ_{ic}^M ($i = I, II$) as follows;

$$\delta_{Io}^M = \delta_0 \cos(\theta) \quad \delta_{IIo}^M = \delta_0 \sin(\theta) \quad (30)$$

$$\delta_{Ic}^M = \delta_c \cos(\theta) \quad \delta_{IIc}^M = \delta_c \sin(\theta) \quad (31)$$

Actually, we may assume the same penalty stiffness values for Mode I and Mode II. As a result, the energy release rate values can be written as;

$$G_I = \frac{\delta_c \delta_o \cos^2(\theta) E O}{2} \quad , \quad G_{II} = \frac{\delta_c \delta_o \sin^2(\theta) E O}{2} \quad (32)$$

By inserting Eqn. (32) in the B-K criterion given in Eqn. (12), the critical displacement value for the mixed-mode van be found;

$$\delta_c = \begin{cases} \frac{2}{\delta_o E O} \left[G_{Ic} + (G_{IIc} - G_{Ic}) \left(\frac{\beta^2}{1 + \beta^2} \right)^\eta \right] & \Leftarrow \delta_I > 0 \\ \delta_{IIc} & \Leftarrow \delta_I \leq 0 \end{cases} \quad (33)$$

Similarly, for the power law criterion;

$$\delta_c = \begin{cases} \frac{2(1 + \beta^2)}{\delta_o E O} \left[\left(\frac{1}{G_{Ic}} \right)^\alpha + \left(\frac{\beta^2}{G_{IIc}} \right)^\alpha \right]^{-1/\alpha} & \Leftarrow \delta_I > 0 \\ \delta_{IIc} & \Leftarrow \delta_I \leq 0 \end{cases} \quad (34)$$

Just as done in the derivation of delamination onset displacement, the resulting critical displacement would be the failure displacement for pure shear due to the removal of the closing displacements.

Upto point, all of the constituents shown in Figure 40 have been determined. However, the requirements for embedding the formulation into the interface element are *traction* and *tangent stiffness matrix* of an interface element. However, before going through the details of them, the *irreversibility concept* of the cohesive zone should be pointed out.

As seen in Figure 41, assume that the loading had started from *point 0* and goes to *point 3* through *point 2* where the delamination emerges and following it the softening occurs. Afterwards, if the element is unloaded, the curve goes directly to *point 0* because the cohesive zone is not fully elastic. Assume that the element is going to be loaded again, then the arrow in Figure 41 would be reversed

and the shaded area is never going to be used again. Therefore, the process is irreversible since some of the energy release rate has been “consumed” during the first loading.

Figure 41: Constitutive relationship with unloading reveals irreversibility.

The definition of *time* should be considered in order take the irreversibility into account as follows;

$$\delta^{\max}(t) = \max_{\tau \leq t} \delta(\tau) \quad (35)$$

Notably, since the finite element analysis solver is an implicit one, the *time* parameter τ in Eqn. (35) is the iterations considering the quasi-static analysis.

Now, recalling the damage mechanics formulation of the cohesive zone given in Eqn. (14), the damage term “*d*” can be defined just by considering the geometrical relations in Figure 41;

$$d = \begin{cases} 0 & \Leftrightarrow \delta^{\max} \leq \delta_o & (INTACT) \\ \frac{\delta_c(\delta^{\max} - \delta_o)}{\delta^{\max}(\delta_c - \delta_o)} & \Leftrightarrow \delta_o < \delta^{\max} < \delta_c \\ 1 & \Leftrightarrow \delta^{\max} \geq \delta_c & (FAILED) \end{cases} \quad (36)$$

Therefore, by putting the damage term of Eqn. (36) into Eqn. (14), it would give the constitutive relationship. However, it is better to use typical representation for the element formulation [107];

$$t_i = D_{ij} \delta_j \quad (37)$$

where $i, j = 1, 2, 3$ which is for 3D case.

For the constitutive relationship, the phenomenon of interpenetration should be included [105]. For this requirement, a function which works like a “checker” is used in order to reveal the status of the opening displacement including the negative one. Actually, this function is a convenient tool, can be defined as;

$$\text{Check}(x) = \frac{\langle -x \rangle}{-x} \quad (38)$$

Therefore with the help of “sign” function, there would be a more robust definition

$$D_{ij} = \bar{\delta}_{ij} \left[(1-d)E_0 + (\bar{\delta}_{ii} \text{Check}(\delta_i)E_0)d \right] \quad (39)$$

Where $\bar{\delta}_{ij}$ ($i, j = 1, 2, 3$) is *Kronecker's Delta* to assure \mathbf{D} matrix to be a diagonal matrix. It may be realized that the definition of function “Check(x)” is a great tool to understand the state of interpenetration. As a result, for the softening region, the damage term, d , would automatically be diminished if there is any closing displacement. Moreover, the Kronecker's delta with subscript “I” is assigned so as to adjust the interpenetration state only in Mode I.

3.2.1.1 Derivation of Tangent Stiffness Matrix

Before starting the derivation, it should be noted that all element calculations are performed in local element coordinate system. Therefore, the transformation of stiffness matrices into global coordinate referenced matrix is not discussed here.

The element formulations require some assumptions easing the process. Firstly, since the interface elements have neglected volume, one may assume that there would be *no body force* acting on the interface element. For the second one, *external force* is never applied to the interface elements because they are located in the inter-laminar region. Hence, one can assume to neglect externally

applied forces on the element. As a result, the only *internal force* \mathbf{R} vector can be found from *the principle of virtual work* [107] as follows;

$$\mathbf{R} = \int_V \mathbf{B}^T \mathbf{t} dV \quad (40)$$

Where \mathbf{B} matrix is *nodal displacement-to-relative displacement matrix*, \mathbf{t} is the traction vector and V is the volume of the interface element. \mathbf{B} matrix is a key matrix that is directly relating the *relative displacement vector* δ to the *nodal displacement* \mathbf{p} as follows;

$$\delta = \mathbf{B}\mathbf{p} \quad (41)$$

It is vital to note that Eqn. (41) involves the rotated or transformed B matrix that is explained in chapter 5.1.2. Note that, the relative displacement vector δ in Eqn.(41) should not be confused with the total relative displacement vector δ given in Eqn.(23) which is the magnitude of the vector δ .

By inserting Eqns. (37) and (41) in Eqn. (40), it follows that;

$$\mathbf{R} = \int_V \mathbf{B}^T \mathbf{D}\delta dV \quad (42)$$

The tangent stiffness matrix can be found from the derivative of the internal force [107] as

$$\mathbf{K}_t = \frac{\partial \mathbf{R}}{\partial \mathbf{p}} = \int_V \mathbf{B}^T \mathbf{D}\mathbf{B} dV + \int_V \mathbf{B}^T \left(\frac{\partial \mathbf{D}}{\partial \mathbf{p}} \right) \delta dV = \mathbf{K}_t^o + \mathbf{K}_t^s \quad (43)$$

where

$$\mathbf{K}_t^o = \int_V \mathbf{B}^T \mathbf{D}\mathbf{B} dV$$

$$\mathbf{K}_t^s = \int_V \mathbf{B}^T \left(\frac{\partial \mathbf{D}}{\partial \mathbf{p}} \right) \delta dV$$

Thus, the constituent \mathbf{K}_t^o can easily be determined since the stiffness matrix \mathbf{D} is already found. In order to determine \mathbf{K}_t^s , the derivative of stiffness matrix \mathbf{D} with respect to global displacements should be undertaken. One may realize that the derivative of \mathbf{B} matrix is neglected. This is due to the reason of using a fully accurate tangent stiffness matrix \mathbf{K}_t is not necessary for DCB test model.

Now, if one expands the derivative of stiffness matrix \mathbf{D} as;

$$\frac{\partial \mathbf{D}}{\partial \mathbf{p}} = \left(\frac{\partial \mathbf{D}}{\partial d} \right) \left(\frac{\partial d}{\partial \mathbf{p}} \right) = \left(\frac{\partial \mathbf{D}}{\partial d} \right) \left(\frac{\partial d}{\partial \delta} \right) \left(\frac{\partial \delta}{\partial \mathbf{p}} \right) \quad (44)$$

From Eqn. (39), the derivative of stiffness matrix with respect to damage scalar, d can be found as:

$$\left(\frac{\partial \mathbf{D}}{\partial d} \right) = \begin{bmatrix} -E0(1 - \text{Check}(\delta_t)) & 0 & 0 \\ 0 & -E0 & 0 \\ 0 & 0 & -E0 \end{bmatrix} \quad (45)$$

Assume that the maximum displacement is attained during loading, in words, the damage evolution is taking place in the *current iteration* ($\tau = t$), then Eqn. (35) would yield $\delta = \delta^{max}$. Therefore, the derivative of damage scalar d with respect to δ can be applicable for Eqn. (36). This yield;

$$\left(\frac{\partial d}{\partial \delta} \right) = \frac{\delta_c \delta_o}{(\delta)^2 (\delta_c - \delta_o)} \quad (46)$$

From Eqn. (41), the last derivative term could be attained as follows;

$$\left(\frac{\partial \delta}{\partial \mathbf{p}} \right) = \left[\frac{\partial \delta}{\partial \delta} \quad \frac{\partial \delta}{\partial \delta} \right] = \left[\frac{\partial \delta}{\partial \delta_1} \quad \frac{\partial \delta}{\partial \delta_2} \quad \frac{\partial \delta}{\partial \delta_3} \right] \mathbf{B} = \left[\frac{\langle \delta_1 \rangle}{\delta} \quad \frac{\delta_2}{\delta} \quad \frac{\delta_3}{\delta} \right] \mathbf{B} \quad (47)$$

As a result, \mathbf{K}_t^s can be defined by putting Eqns. (45), (46), and (47) into Eqn. (43).

Figure 42: Constitutive relation minimum features.

Now, it is time to grant the tangent stiffness matrix in terms of loading, unloading, damaging and the interpenetration prevention features as shown in Figure 42. As a summary;

1. **Intact Region:** $\delta^{max} \leq \delta_o$ and at any time τ the response is similar to a typical linear law;

$$\mathbf{K}_t = \int_V \mathbf{B}^T \begin{bmatrix} E0 & 0 & 0 \\ 0 & E0 & 0 \\ 0 & 0 & E0 \end{bmatrix} \mathbf{B} dV \quad (48)$$

2. **Softening Region:** $\delta_o < \delta^{max} \leq \delta_c$, the tangent stiffness is varying from secant to the tangent one. Therefore, the formulation should be divided into two.

- a. Unloading/Reloading with no damage evolution; $\delta < \delta^{max}$

$$\mathbf{K}_t = \mathbf{K}_t^o = \int_V \mathbf{B}^T \begin{bmatrix} (1-d)E0 + dE0Check(\delta_\tau) & 0 & 0 \\ 0 & (1-d)E0 & 0 \\ 0 & 0 & (1-d)E0 \end{bmatrix} \mathbf{B} dV \quad (49)$$

- b. Damage evolution (loading state); $\delta = \delta^{max}$

$$\mathbf{K}_t = \mathbf{K}_t^o + \mathbf{K}_t^s \quad (50)$$

where \mathbf{K}_t^s can be written explicitly.

$$\mathbf{K}_t^s = \left(\frac{\delta_c \delta_o}{(\delta)^2 (\delta_c - \delta_o)} \right) \int_V \mathbf{B}^T \begin{bmatrix} -E0(1 - \text{Check}(\delta_1)) & 0 & 0 \\ 0 & -E0 & 0 \\ 0 & 0 & -E0 \end{bmatrix} \cdot \begin{bmatrix} \langle \delta_1 \rangle \\ \frac{\delta}{\delta} \\ \frac{\delta_2}{\delta} \\ \frac{\delta_3}{\delta} \\ \frac{\delta}{\delta} \end{bmatrix} \cdot \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix}^T \mathbf{B} dV \quad \mathbf{T}$$

this yields;

$$\mathbf{K}_t^s = - \int_V \mathbf{B}^T \left(\frac{\delta_c \delta_o E0}{(\delta)^3 (\delta_c - \delta_o)} \begin{bmatrix} (1 - \text{Check}(\delta_1))\delta_1\delta_1 & (1 - \text{Check}(\delta_1))\delta_1\delta_2 & (1 - \text{Check}(\delta_1))\delta_1\delta_3 \\ (1 - \text{Check}(\delta_1))\delta_2\delta_1 & \delta_2\delta_2 & \delta_2\delta_3 \\ (1 - \text{Check}(\delta_1))\delta_3\delta_1 & \delta_3\delta_2 & \delta_3\delta_3 \end{bmatrix} \right) \mathbf{B} dV$$

3. Failed Region: $\delta^{max} > \delta_c$, only the interpenetration can be provided to the system.

$$\mathbf{K}_t = \int_V \mathbf{B}^T \begin{bmatrix} \text{Check}(\delta_1)E0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \mathbf{B} dV \quad (51)$$

CHAPTER 4

CONVERGENCE ISSUE AND ARC-LENGTH METHOD

4.1 Convergence Issue

Apparently, the most challenging feature of the Cohesive Element Method is the convergence issue. Therefore, this section is dedicated for the discussion of numerical solution and the properties of CZM spawning divergences. Importantly, the discussed items in this section are to be checked and used in our study.

4.1.1 “Trouble” in CZM and Literature Survey

The local softening behavior of the interface elements results in a global softening response of the structure [2]. As a result, this causes “hard-to-catch” equilibrium points. Naming, severe *snap-back* and *snap-through* behaviors are observed [21-22]. In addition to the severe nonlinearities, there are also oscillations in the equilibrium path, because of the positive slope of the total potential energy [22]. In addition to the softening, the high penalty stiffness requirement overshoots the equilibrium [12] and even causes numerical instabilities. Consequently, CZM requires considerable study in numerical solution scheme.

The structural responses like *snap-through*, *snap-back*, *brittle collapse* and *ductile collapse* are illustrated in Figure 43. Widely used numerical solution methods like *Full* or *Modified Newton-Raphson* (N-R) methods applies “fixed” loading during iterations. Thus, none of them have ability to deal with problems involving snap-through, snap-back, brittle collapse and ductile collapse behavior [22,61].

Figure 43: (a) Snap Back (b) Snap Through (c) Brittle Collapse (d) Ductile Collapse cases [22].

For a deeper understanding of these discrepancies, it would better to consider each case individually from Figure 43. Initially, all cases start with *point A* which is last converged position. For Figure 43a, snap-back behavior is shown where a displacement controlled, with non flexible iterative method, like N-R is only able to catch *point C* while missing the intermediate equilibrium points like *point B*, staying outside the constant displacement shown as dashed line. Similarly, in the case of Figure 43b, any non-flexible load controlled method could only catch *point C* instead of *point B* for a snap-through case. For the cases in Figure 43c and Figure 43d, constant load line is not able to catch the equilibrium points located on the right hand side. Even for the top points of the curves, tangent stiffness matrix diminishes. Consequently, this yield “goes to infinity” situations, or at best, overshooting the points where the convergence is impossible. Therefore, as to be discussed in the following paragraphs, a “constraint equation” should be embedded into governing equations to move around such problematic points. This is accurately done by *Arc-Length Method*, which circumvents problematic cases with great flexibility to catch sharp snap-back and snap-through cases [22].

In the current study, the solution is performed by a commercial non-linear solver MSC MARC 2005r3 [64]. The solution in our study is performed by *quasi-static* loading in which the external loads and the prescribed displacements are supposed to be continuously adjusting themselves so as to be in the state of equilibriums progressively in each increment [61]. However, one could claim that in reality, loads do not adjust themselves to gain “flexibility”, even if they are applied quasi-statically [20]. One would also suggest that such limit points might induce dynamic phenomena, like

“dynamic snaps” from one to another stable branch of the equilibrium path, or with a final structural collapse just like N-R does as shown in Figure 43b. This method is being used for cohesive element method, which is called *hybrid static/dynamic method* [20]. Just for a reference, this procedure is also explained hereafter briefly since it shows a candidate CZM solver for the future.

The methodology of hybrid method is for “jumping” over snap through areas by appending dynamics. In words, the procedure goes up to limit points by using standard methods. Afterwards, when a current stiffness parameter reaches a critical point –that depicts the critical point is inside the vicinity – then the perturbation load is increased monotonically while the procedure transits from statics to dynamics with a prescribed initial velocity [20]. This procedure is illustrated in Figure 44.

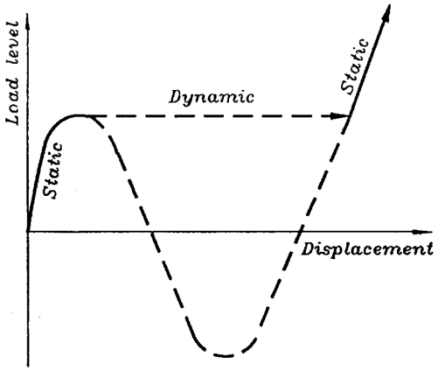

Figure 44: Hybrid static/dynamic solution procedure on a snap-through region [20].

As understood from the original name, the hybrid method involves both dynamic and static solution phases. The dynamic solution procedure could be explicit or implicit [20]. It is worth noting that an explicit approach within a quasi-static analysis would have the advantage compared to the implicit methods, in the way of the equilibrium not having to be rigorously satisfied at each increment [2]. Yet, specific to the cases where small dynamic regions with high nonlinearities, the hybrid method is a promising method for the future studies.

4.1.2 Coping with Convergence Problem

There are suggestions to enhance the convergence rate of CZM. In this section, they are mentioned in the way that literature takes them into account. Reminding that, these suggestions are called as *artificial modifications* and revisited in our study.

The numerical solution of a DCB test by CZM is directly related to the mesh characteristic. If one investigates Figure 45, it can be seen that different responses depending on the mesh size may exist in the same test. The coarser mesh size, however, shows equilibrium points in harsh snap backs and relatively mild snap-through effects on the solution [1,59]. This effect is avoided in our study by applying the suggestions about the mesh size.

Figure 45: (a) Mesh sensitivity load versus displacement results in application point for a finite element model of DCB test using CZM [59] and 4x50 mesh size region (b) A closer look for the Snap-Back (S.B.) and Snap-Through (S.T.).

In addition to the mesh size effect, the maximum opening traction magnitude is also influencing the convergence rates as shown in Figure 46. Actually, this is due to the fact that, as the maximum traction value increases, the length of the cohesive length increases [95]. Therefore, one does not need to decrease the mesh size in order to fulfill the mesh requirements for convergence. Otherwise, the decreasing mesh size would yield longer solution times. Hence, the performance would benefit from lowering the interfacial strength. However, as expected, the delamination initiation would be underestimated if the interfacial strength was lowered [39].

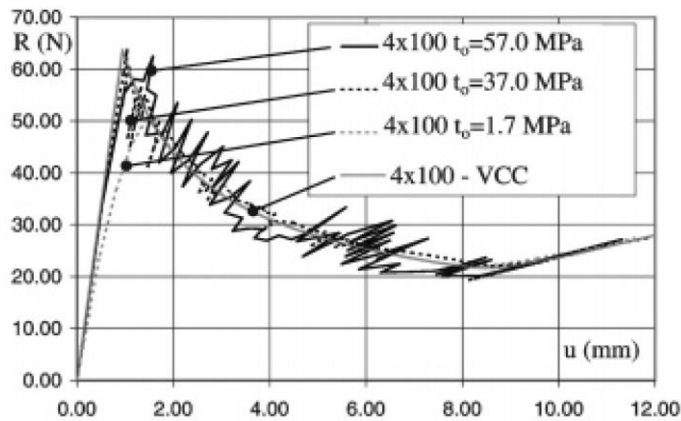

Figure 46: Tip Load - Displacement curve for DCB test and interfacial strength effect [59].

Beside the mesh size, convergence is greatly being affected by the *penalty stiffness*. As mentioned before, the interface element should not influence the behavior of the structure. To do that, penalty stiffness is supposed to be as high as possible. However, the high penalty stiffness values cause convergence problems and even singularities during the solution. On the other hand, lower stiffness values results in incorrect results as shown in Figure 47. Hence, this effect is also considered in our study.

Figure 47: Effect of penalty stiffness value K in a DCB test model with 2.5mm mesh size [95].

To sum up, such non-linearities would essentially lead to sophisticated non-linear solver procedures. The best non-linear solver to overcome such difficulties is perhaps the arc-length method. The

specific method for the solution is the *Spherical Arc-Length Method* that is discussed elaborately in the next section.

4.2 Arc-Length Method

The arc-length method is re-derived in this section. As done for all of the derivations in our study, the derivation starts from the very basics, which is Newton-Raphson method for numerical solutions. Moreover, since Spherical Arc-Length Method is used, the derivation of that specific kind is emphasized.

Therefore, Newton-Raphson method formulates the numerical solution procedure as follows [22];

$$\mathbf{K}_t \Delta \mathbf{p} = \mathbf{R} - \mathbf{F} = \mathbf{g} \quad (52)$$

where \mathbf{K}_t is *tangent stiffness matrix* which is a function of *displacement vector* \mathbf{p} and the *incremental displacement* is $\Delta \mathbf{p}$. *Residual force* (or *non-balanced force*), which is the difference between *internal forces* \mathbf{R} , and *externally applied loads* \mathbf{F} , is \mathbf{g} . Therefore, the convergence of an increment would be assumed to be achieved if the residual force is under a certain limit called *tolerance*. Actually, N-R procedure accomplishes converged increments by seeking incremental displacements, $\Delta \mathbf{p}$, which results in residual forces under the tolerance. To do that, updating of internal load vector and tangent stiffness matrix are the key points that determine the convergence rate. The calculation of both the tangent stiffness matrix and the internal force are given in the previous chapter.

As mentioned before, N-R method fails to find solutions in specific non-linear behaviors as illustrated in Figure 48a. Yet, it was suggested that if one “augments a constraint” equation to be followed by loading scheme, the convergence would be achieved just by controlling that augmented equation as shown in Figure 48b. It can be revealed that the augmented curve is an “arc” [22] of which center is located at the last converged point. Therefore, the external loading force \mathbf{F} is following this arc to catch the equilibrium points.

Figure 48: (a) Newton-Raphson method iterates (b) Arc-Length method iterates

Starting from pioneering work of Riks [81-82] and Wempner [101], it can be proposed to add an additional constraint by enforcing a combined norm of changes in displacements and loads. In fact, this is the point where the arc length method starts to be distinguished from others. In the arc-length method, the external load vector becomes a function [92];

$$\mathbf{F}(\lambda) = \lambda \mathbf{f} \tag{53}$$

Where λ is the *load level* and \mathbf{f} is *reference load vector* which is a fixed parameter throughout the solution and indeed, determined by hand. Therefore, the discrete set of nonlinear equilibrium equations representing a structural system becomes functions of both the displacement and the load level parameter in the arc length method [61].

After this point, the equations will include iterative and incremental symbols in order to relate to the procedure for stepping. With this objective, the superscript “ n ” and subscript “ i ” correspond to the increment number and the iteration number, respectively. Moreover, “ δ ” corresponds to the rate of change of the parameter between the current iteration “ i ” and the previous iteration, “ $i-1$ ”. Whereas, “ Δ ” corresponds to the difference between the current iteration and last converged increment, “ $n-1$ ”. Mathematically speaking;

$$\Delta X_i^n = X_i^n - X_i^{n-1} \quad (54)$$

$$\delta X_i^n = X_i^n - X_{i-1}^n$$

where “X” are the terms for the load level or the displacement because they are the only iterative/incremental variable for the arc length method. Additionally, the terms without any subscript would imply no iterative relation, which is the converged positions, or analytical representation works for every increment or iteration.

At this point, the residual force \mathbf{g} can be re-written in a more explicit form as [22]

$$\mathbf{g}_i^n(\lambda_i^n, \mathbf{p}_i^n) = \mathbf{R}(\mathbf{p}_i^n) - \lambda_i^n \mathbf{f} \quad (55)$$

Since the load level would vary throughout the process in arc-length methods just by controlling the load level parameter λ [81]. Hence, as going to be seen in the following paragraphs, the objective would be to find the load parameter in arc-length method.

The Arc-Length Method is best described by Figure 49. In order to do that, one should define the parameters that should be represented by known parameters; tangent stiffness matrix \mathbf{K}_t , residual force \mathbf{g} , reference load \mathbf{f} and the *radius of the arc*, Δl . The radius of the arc is controlled by the solver in order to catch the mid-points. Such details for the user control on convergence are given in Appendix C.

$$\delta \bar{\mathbf{p}}_i^n = -(\mathbf{K}_t^{-1})_i^n \mathbf{g}_i^n \quad (57)$$

$$\delta \hat{\mathbf{p}}_i^n = (\mathbf{K}_t^{-1})_i^n \mathbf{f} \quad (58)$$

where $(\mathbf{K}_t^{-1})_i^n$ is the inverse of tangent stiffness matrix. Notably, the minus sign for the tangent stiffness matrix in Eqn. (57) is originated from the definition of residual force direction as shown in Figure 50.

Figure 50: Sign conventions for internal force and residual force and arc-length method iterates.

If the modified N-R method is used, the tangent stiffness is calculated in the predictor phase [22] and remains fixed during the iterations. In our study, the iterative procedure was taken as full N-R method in which the tangent stiffness values are calculated at each iteration. Actually this is the reason why the term \mathbf{K}_t is shown with both iterative and incremental symbols, i and n , respectively. Just for a reference, the tangent stiffness could also be the secant stiffness as proposed in [75].

Now, during an increment, one can relate the incremental steps to the previous steps. In order to cover the previous steps, the relation of the iterative displacements can be written as follows [22];

$$\Delta \mathbf{p}_i^n = \Delta \mathbf{p}_{i-1}^n + \delta \mathbf{p}_i^n \quad (59)$$

From Eqn. (56) and (59);

$$\Delta \mathbf{p}_i^n = \Delta \mathbf{p}_{i-1}^n + \delta \bar{\mathbf{p}}_i^n + \delta \lambda_i^n \delta \hat{\mathbf{p}}_i^n \quad (60)$$

In Eqn. (60), it can be seen that $\delta \bar{\mathbf{p}}_i^n$ and $\delta \hat{\mathbf{p}}_i^n$ are known, since the tangent stiffness and the residual regarding to the previous load level is known. All of the items except the load level change are known for that iteration, $\delta \lambda_i^n$, which is found by the constraint equation.

The way the load level grows depends on the path geometries that are proposed by Crisfield [19], Riks [81], Wempner [101] and Ramm [75]. In Figure 49 and Figure 50, the most well-known arc length method, Crisfield's *spherical arc-length method* [18] is illustrated. The name "spherical" reveals the 3D feature of the displacements. However, since our study does not involve the third dimension, the sphere indeed becomes a circle.

Crisfield defined the spherical constraint geometry by introducing a spherical arc which is kept constant during an increment [18] given by;

$$(\Delta \mathbf{p}_i^n)^T \Delta \mathbf{p}_i^n + \Delta \lambda_i^n \mathbf{f}^T \Delta \lambda_i^n \mathbf{f} = \Delta l^2 = const \quad (61)$$

An equally effective and simpler equation can be obtained by neglecting the effect of forces [19];

$$(\Delta \mathbf{p}_i^n)^T \Delta \mathbf{p}_i^n = \Delta l^2 = const \quad (62)$$

By putting Eqn. (60) into Eqn. (62), one can obtain the *quadratic equation* for the iterative change of the load level, $\delta \lambda$. Moreover, that equation is also called as *augmented equation* [19] that is represented by;

$$C_2 (\delta \lambda_i^n)^2 + C_1 (\delta \lambda_i^n) + C_0 = 0 \quad (63)$$

where;

$$C_0 = (\Delta \mathbf{p}_{i-1}^n)^T \Delta \mathbf{p}_{i-1}^n + 2(\Delta \mathbf{p}_{i-1}^n)^T \delta \bar{\mathbf{p}}_i^n + (\delta \bar{\mathbf{p}}_i^n)^T \delta \bar{\mathbf{p}}_i^n - \Delta l^2$$

$$C_1 = 2(\hat{\delta \mathbf{p}}_i^n)^T (\Delta \mathbf{p}_{i-1}^n + \Delta \hat{\mathbf{p}}_i^n)$$

$$C_2 = (\hat{\delta \mathbf{p}}_i^n)^T \hat{\delta \mathbf{p}}_i^n$$

There are two roots of Eqn. (63) which are the iterative load increments; $(\delta \lambda_i^n)_1$ and $(\delta \lambda_i^n)_2$. To avoid going back to the original load-deflection curve, the angle between before and after the current iteration should be positive [61]. Additionally, the root selected gives convergence or divergent solutions [61,92]. This avoidance of the going back is called the *doubling back action* that is illustrated in Figure 51.

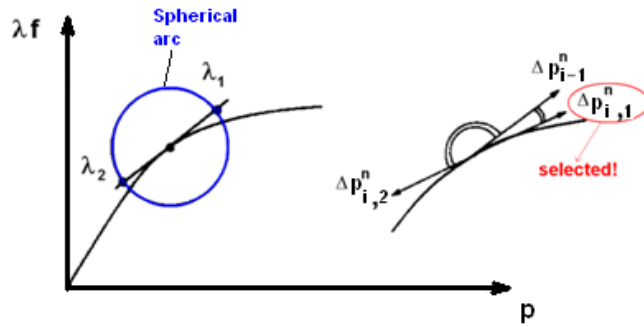

Figure 51: Doubling back phenomenon and solution [19].

According to the original work of Crisfield [22], the root is selected according to the angle between the previous incremental displacement and the searched incremental displacement vectors [19] as

$$\angle(\Delta \mathbf{p}_i^n)^T \Delta \mathbf{p}_{i-1}^n = \min \quad (64)$$

It would be better to define this angle in a more explicit way [61] as

$$\cos \phi_1 = \frac{((\Delta \mathbf{p}_i^n)_1)^T \Delta \mathbf{p}_{i-1}^n}{\Delta l} \quad (65)$$

$$\cos \phi_2 = \frac{((\Delta \mathbf{p}_i^n)_2)^T \Delta \mathbf{p}_{i-1}^n}{\Delta l}$$

However, the minimum angle requirement would not be adequate for some cases like very harsh snap-backs. To deal with that there are some modifications as the selection of the root like the one shown in Figure 52. As one can observe that although the angle of root λ_1 is smaller than the root λ_2 , the solution would not be correct for that basis. Therefore, another criterion is used that the root yielding the *minimum residual* is the “correct” root [18].

Figure 52: Sharp-Snap Back with two possible roots [18].

As seen in Figure 52, although the angle between $\Delta \mathbf{p}_{i-1}^n(\lambda_1)$ and $\Delta \mathbf{p}_{i-1}^n$ is smaller than the angle between $\Delta \mathbf{p}_{i-1}^n(\lambda_2)$ and $\Delta \mathbf{p}_{i-1}^n$, the result would be wrong if λ_1 is selected. Therefore, there ought to be another criterion that is comparing the residuals instead. Unfortunately, MSC.MARC 2005r3 does not involve such a check [61]. Yet, harsh snap-backs have not been seen in our study. Also, fortunately, MARC uses another method to deal with the deficiency of sharp snap-backs, the root which is closer to the approximate linear solution is selected [61], as discussed in the following paragraphs.

The disadvantage of the equation suggested by Crisfield is the introduction of quadratic equation hatching two roots and thus there is a need for an extra effort to select appropriate root among the calculated ones if two real roots exist. Moreover, selection of the roots would yield divergence if the

selected root was wrong. Especially, this situation arises when the contribution of iterative displacements are very large in comparison to the arc length. Fortunately, our study does not include such high steps, which is going to be discussed more deeply later. Even if there were such cases, for the sake of reference, this can be avoided in most cases by setting sufficiently small values of the error tolerance on the residual force [61].

These problems are circumvented in the Riks/Ramm procedure by *linearization* [75,81]. The difference is that while Crisfield imposes the constraint as a quadratic equation, Riks and Ramm linearizes the constraint [75,81]. Actually, those methods are generally called the *linearized arc-length method* [22]. The contrast between those approaches are given in Figure 53.

Figure 53: Crisfield's spherical arc length method and Riks/Wempner's linearized method

Riks/Wempner [81-82] method uses *derivative* of the arc during *predictor iteration*, whereas, Ramm [75] uses tangents at each iteration in an increment. However, Crisfield's spherical arc-length method is much more versatile than the linearized methods. Therefore, spherical arc-length method is selected in our study.

CHAPTER 5

INTERFACE ELEMENT FORMULATION AND BENCHMARK TEST

5.1 Finite Element Implementation

This section is specified for the interface element that is developed to be used in the benchmark test model. For the finite element implementation, *plane strain* assumption is used with both a 6-node quadratic (Figure 54) and 4-node linear line (1D) interface elements. Since the 4-node element implementation is similar to 6-node, the formulations for 4-node interface element is given in Appendix A. Schellekens, de Borst [87] and Crisfield [59] suggested the use of 6-node interface elements.

Figure 54: 6-node quadratic interface element with nodes and integration points.

As seen in Figure 54, the green circular dots are the *nodes* and the remaining red rectangular symbols are the *integration points*. The node numbering (i) is done according to the counter-clockwise positioning. Moreover, one may realize that the elements are represented in 2D geometry, yet formulated as 1D element in which the upper and the lower nodes are coincident. This is due to the fact that the element uses “relative displacement” instead of strains. Hence, zero-thickness element showing 1D geometry can be developed without any geometrical conflict.

There are three coordinate systems used for each interface element definition (Figure 54). The first one is the *global coordinates* shown in capital letters, (X_i, Y_i) which is required for the global stiffness matrix assembly of the entire FE model. Following, the *local coordinate system* is defined for cohesive formulations. Note that, the local coordinate system is illustrated in lower case letters (x_i, y_i) and the origin is located at the centroid of the element. Finally, the *element coordinate system* (ξ) is typically used for *shape function definition*, which is to be used in *numerical integration scheme*. It can be realized that since the interface element is actually a 1D element, there is no secondary element coordinate axis, like η [107].

The reason why interface elements should have zero thickness is not to influence the specimen dimensions by occupying a volume. Therefore, the nodes that are facing each other are to be coincident. The numerical integration scheme that is used in our study is the *Newton-Cotes integration scheme*, using sets of nodes formed by coincident nodes. All geometrical and numerical operations are to assure the best convergence rate, which are suggested by Schellekens and de Borst [87].

The user defined element is embedded in MSC MARC 2005r3 by using a *user-defined element subroutine* called USELEM which is outputting the *internal force vector*, *external force vector* and *tangent element stiffness matrix* to perform the non-linear analysis [61,63] as discussed in the previous chapter.

5.1.1 Shape Function Derivation for Quadratic Interface Element

Since the developed element is a zero thickness interface element, ordinary *quad element* [62] shape functions cannot be used. Therefore, the corresponding shape function derivation is given here. It should be noted again that the shape function derivation for 4-node linear interface element is given in Appendix A.

It is found that [72,87,95-96] the *Gaussian Integration* scheme would yield spurious oscillations in the traction profile, and therefore, it is suggested to use *Newton-Cotes* integration scheme instead. Since 6-node quadratic interface element is used, there would be three Newton-Cotes integration points as shown in Figure 54. Thus, the integration points are located with respect to the element coordinates as; $\xi = -1$, $\xi = 0$ and $\xi = 1$, from left to right, respectively. Actually, one can realize that these integration points are “located over” the corresponding nodes. Therefore, the integration is identical with the *lumped integration* scheme that is also used frequently in CZM applications for higher order elements [87].

Actually, the interface element is treated as 1D element by grouping the nodes in that each group has two nodes used for calculating the relative displacement on that integration point. Consequently, each node set would output one displacement vector which makes the six node element treatable as 1D element. Mathematically, the node grouping can be performed by the following relation;

$$(i, N - i + 1) \in s_i \quad , \quad i = 1, 2, \dots, N/2 \quad (66)$$

where N is the total number of nodes, i is the node number and s is the node set number in which the first term shall be the *lower node* and the latter will be the *upper node*. For the 6-node quadratic element ($N = 6$), there are three number of different node sets; (1,6), (2,5) and (3,4) as illustrated in Figure 55.

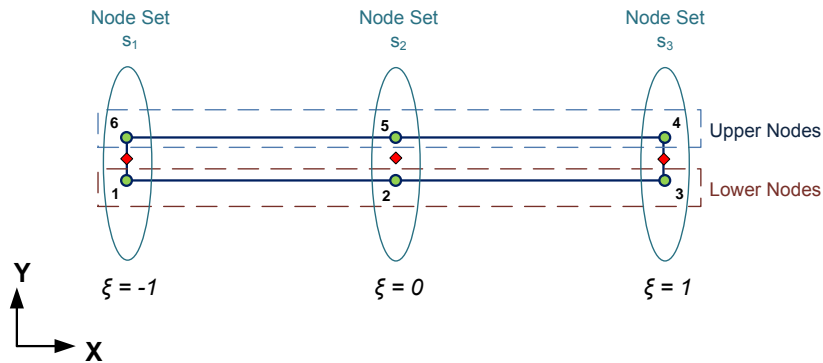

Figure 55: Grouping and node sets in 6-node quadratic interface element

The Figure 56 presents a *quadratic line element* which can be also applicable just by taking the node groups as individual “representative node”. Actually, in our finite element model, the interface element resembles a line with three coincident nodes.

Figure 56: Quadratic line element (The node sets on integration points is a rectangle with a circle)

One may start to derive the shape function by defining the behavior of the element. Hence, the interpolation equation of quadratic line element can be generalized as a quadratic function as follows [107];

$$\phi(\xi) = a_0 + a_1\xi + a_2\xi^2 \quad (67)$$

The shape functions should have the same degree given in Eqn. (74). By obtaining zero in the node sets s_2 and s_3 , the candidate shape function for node set 1 becomes;

$$N_1(\xi) = C\xi(\xi - 1) \quad (68)$$

In order to give unity at node set 1 ($\xi = -1$), the constant C can be found as;

$$N_1(-1) = C(-1)(-1 - 1) = 1 \quad \Rightarrow \quad C = \frac{1}{2} \quad (69)$$

As a result the first of the shape function is;

$$N_1 = \frac{1}{2}(\xi^2 - \xi) \quad (70)$$

The remaining shape functions for s_2 and s_3 can be found as;

$$N_2 = 1 - \xi^2 \quad , \quad N_3 = \frac{1}{2}(\xi^2 + \xi) \quad (71)$$

Finally, if one may sum the shape functions, it would give unity, such that; $N_1 + N_2 + N_3 = 1$. Therefore, the shape functions derived are appropriate for the quadratic line interface element.

5.1.2 Element Kinematics

The interface elements can be modeled in any orientation like shown in Figure 57. Therefore, the transformation from local to global coordinates is required for the consistent element matrices like stiffness matrices and internal force vectors. Hence, this section is dedicated for this objective.

Figure 57: Rotated interface element.

The solution procedure selected for our study is *Total Lagrangian Solution* in which the effect of displacement terms would be neglected [61]. Since the DCB test does not face with high displacements, the appropriate solution procedure is the Total Lagrangian procedure. In this procedure, any transformation matrix \mathbf{T} that relates global to local coordinate systems would be assumed to be insensitive to displacement, \mathbf{p} . Therefore, the transformation is taken into account only for the initial configuration. In other words, the following discussion does not consider the incremental variations. However, it should be noted that although this formulation is based on the initial element geometry, the incremental stiffness matrices are formed to account for previously developed stress and changes in geometry [61].

Assume that the modeling of interface element is not aligned with (global) X coordinate and modeled with an offset from the global origin as shown in Figure 57. In this case, the *misalignment angle*, θ is to be applicable easily just by recalling the element as 1D without regarding the 2D geometry. Therefore, since the displacement term is neglected for the transformation matrix, the misalignment angle would result in *transformation matrix*, \mathbf{T} .

The reference line representing the orientation of the element is line AB in Figure 57. It passes over the mid-points of node set 1 and node set 3. Therefore, the location of A and B can be defined in terms of global coordinates (X_i, Y_i) where i is the node number;

$$A = \left(\frac{X_6 + X_1}{2}, \frac{Y_6 + Y_1}{2} \right), \quad B = \left(\frac{X_4 + X_3}{2}, \frac{Y_4 + Y_3}{2} \right) \quad (72)$$

The misalignment angle would be negative or positive as shown in Figure 58. Therefore, the angle should be defined in tangent for considering the sign of the angle θ ;

$$\theta = \tan^{-1} \left(\frac{Y_3 + Y_4 - Y_1 - Y_6}{X_3 + X_4 - X_1 - X_6} \right), \quad 0 < \theta \leq 90^\circ \quad (73)$$

Figure 58: Possible misalignment angle configurations.

One may observe from Figure 58 that the elements located in the negative X direction would have the same angle θ , yet with reversed \overline{AB} definition. This is due to the fact that the node numbering would change and \overline{AB} would be different. Hence, the definition in $+X$ direction would compensate all of the orientations.

Typically, the transformation matrix, \mathbf{T} can be defined as;

$$\mathbf{T} = \begin{bmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{bmatrix} \quad (74)$$

Now, assume the node i is moved by means of *global displacement vector*, \mathbf{P} . After this point, the directions, both for global and local, X and Y are going to be labeled by subscript 2 and I , respectively. Therefore, the total nodal displacement vector in global coordinates is as provided by MARC [61];

$$\mathbf{P} = \begin{bmatrix} P_{12} \\ P_{1I} \\ \vdots \\ P_{62} \\ P_{6I} \end{bmatrix} \tag{75}$$

As observed from Eqn. (75), the direction indices are ordered from 2 to I because the subscript is representing Y direction which is provided by the FE solver in this sequence.

Figure 59: Nodal displacement vector in local coordinates.

As mentioned before, the interface element uses the relative displacement. Therefore, the *relative displacement field in global coordinates*, Δ can be defined for each node set j by the help of shape functions can be found as follows;

$$\Delta^j = \mathbf{N}_j \left(\mathbf{U}_{top}^j - \mathbf{U}_{bottom}^j \right), \quad j=1,2,3 \quad (76)$$

Where \mathbf{U}_{top}^j and \mathbf{U}_{bottom}^j are the nodal global displacement vectors for the upper and lower node of the node set j referring to Figure 55 and N_j is the matrix form of shape functions for the node set j ;

$$\mathbf{N}_j = \begin{bmatrix} N_j & 0 \\ 0 & N_j \end{bmatrix}, \quad j=1,2,3 \quad (77)$$

Yet, one should have a relating matrix that associates Δ (Eqn. (75)) and \mathbf{P} (Eqn. (75)), directly by one operation. To do that, the *global relative displacement to global nodal displacement matrix* \mathbf{B}' can be defined as follows;

$$\mathbf{B}' = \begin{bmatrix} -N_1 & 0 & -N_2 & 0 & -N_3 & 0 & N_3 & 0 & N_2 & 0 & N_1 & 0 \\ 0 & -N_1 & 0 & -N_2 & 0 & -N_3 & 0 & N_3 & 0 & N_2 & 0 & N_1 \end{bmatrix} \quad (78)$$

which can be used to relate Δ to \mathbf{P} as follows;

$$\Delta = \mathbf{B}'\mathbf{P} \quad (79)$$

However, it should be required to obtain *the local relative displacement vector*, δ defined in local coordinates. Therefore, through the transformation matrix \mathbf{T} , one can write;

$$\delta = \mathbf{T}\Delta \quad (80)$$

From Eqns. (79) and (80);

$$\delta = \mathbf{T}\mathbf{B}'\mathbf{P} = \mathbf{B}\mathbf{P} = \begin{bmatrix} \delta_2 \\ \delta_1 \end{bmatrix} \quad (81)$$

where \mathbf{B} matrix is the *local relative displacement-to-global nodal displacement matrix* which is the one used in the numerical integration so as to find the element tangent stiffness matrix \mathbf{K}_t and the internal force vector \mathbf{f} .

5.1.3 Numerical Integration

The numerical integration scheme required in the element formulations are for the *internal force vector* and the *element tangent stiffness matrix*. Note that, the integration scheme defined in this section is for 6-node quadratic interface element. A corresponding scheme for 4-node interface element is given in Appendix A.

Integration expressions for the internal force vector \mathbf{R} and the element tangent stiffness matrix \mathbf{K}_t can be described in terms of element coordinate system as follows [107];

$$\mathbf{R} = \int_V \mathbf{B}^T \mathbf{t} dV = \int_A \mathbf{B}^T \mathbf{t} w dA = w \int_{-1}^1 \mathbf{B}^T \mathbf{t} \det(J) d\xi \quad (82)$$

$$\mathbf{K}_t = \int_V \mathbf{B}^T \mathbf{D}_t \mathbf{B} dV = \int_A \mathbf{B}^T \mathbf{D}_t \mathbf{B} w dA = w \int_{-1}^1 \mathbf{B}^T \mathbf{D}_t \mathbf{B} \det(J) d\xi \quad (83)$$

Where w is the width of the specimen and $\det(J)$ is the determinant of *Jacobian matrix*, [107] which can be generalized for 1D integration scheme as the *half-length of the element* $l_e/2$ [72]. It can be defined as;

$$\text{Det}(J) = l_e / 2 = \frac{\sqrt{(X_3 + X_4 - X_1 - X_6)^2 + (Y_3 + Y_4 - Y_1 - Y_6)^2}}{4} \quad (84)$$

Considering the 6-node element having three integration points, it is obvious that the numerical integration scheme would be the *3-point Newton-Cotes* integration method. To do that, the *Simpson 'one-third' rule* is applied for the integration as follows [107];

$$\int_{-1}^1 g(\xi) \approx \sum_{j=1}^3 H_j g(\xi_j) \quad (85)$$

Where H_j is the coefficients and ξ_j is the integration point locations and j is node set value. Specifically, $H_1 = H_3 = 1/3$ while $H_2 = 4/3$ and $\xi_1 = -1$, $\xi_2 = 0$, $\xi_3 = 1$.

5.2 Benchmark Test

The benchmark test is a DCB mode I test, composed of T300/977-2 unidirectional layers, that was performed by Morais et al. [70]. The reason for selecting this test is that many authors [13,43,59,96] studied the convergence problems used the test performed by Morais et al.. As a result, the results would be discussed elaborately and easily.

5.2.1 Finite Element Model of Double Cantilever Beam (DCB) Test

The specimen has 150 mm length and 20 mm thickness with 55 mm initial crack dimension. Each arm is 1.98 mm in height with the stacking of $[0^\circ]_{12}$. Hence, the total stacking is $[0^\circ]_{24}$, figuring 3.96 mm, while unit ply thickness is 0.165 mm. The dimensions of the DCB specimen and the material properties of T300/977-2 are summarized in Figure 60 and Table 2, respectively.

Figure 60: DCB specimen dimensions.

Table 2: Material and interfacial properties of DCB test specimen in T300/977-2 [32]

<i>Material Properties of DCB Test (T300/977-2)</i>

0.352 N/mm	1.002 N/mm	60 MPa	60 MPa

5.2.2 Finite Element Model

The finite element model used in this study is a two dimensional *plane strain* model. The modeling of DCB cantilever is performed in MSC PATRAN 2005 r2. It should be noted that the test apparatus is not modeled.

For our study, there are two different models in the benchmark tests;

- *Model using 4-Node Linear Interface Elements*
- *Model using 6-Node Quadratic Interface Elements*

The *connectivity details* of the above models are different. The interface elements are connected with the DCB body in different number of nodes. Therefore, the total number of elements in each model is also different. Such differences are aroused due to the fact that the meshes are modeled with *Quad* elements having 8 nodes (Figure 61) for the model using 6-node interface element, whereas 4-node one uses *Quad* elements having 4 nodes (Figure 83) [62]. This requirement is for the compatibility of the elements. The details of mesh compatibility yield different performance characteristics. This effect is one of the objectives in our study and going to be discussed elaborately in the following sections.

As mentioned earlier, an average mesh size determination of the model is mainly driven by the requirement of the minimum number of interface elements for obtaining convergence [96]. As suggested by Turon et al. [96], the minimum required element size can be obtained from Eqn. (15). From the material properties listed in Table 2, Turon et al. suggested to use $M = 0.88$ value, as a result, the expected cohesive zone length would be;

$$l_{cz} = \left(11000MPa \frac{0.352N/mm}{(60MPa)^2} \right) (0.88) = 0.95mm$$

In order to compensate the requirement of more than 3 elements, the minimum mesh size , l_e , should be;

$$\text{Min. } l_e = \frac{0.95\text{mm}}{3} = 0.32\text{mm}$$

Therefore, a mesh width, smaller than 0.32 mm, is supposed to give converged results. Although this is a general approach, the mesh size for guaranteed converged is still blurry [27,96]. Moreover, this suggestions is for plane stress models. Therefore, it would be better to decrease the mesh size of 0.32 mm while the solution time is attainable. As a result, mesh size of 0.25 mm for 6-node interface and 0.125 mm mesh sizes for 4-node are chosen, arbitrarily. Consequently, the interface elements will have at least those widths. The reason behind the mesh size difference between the 6-node and 4-node models is so as to sustain the same number of nodes with the same mesh morphology as much as possible.

Actually, one may use such fine meshes that the solution would be guaranteed to reach convergence. However, in that case, the solution of the model would take too much time. Hence, one may use as less degrees of freedom as possible in order to decrease the solution time. Therefore, varied mesh size is used in this study to shorten the solution period. The details of the mesh are briefly explained in the following section for 6-node interface model, whereas, the details of the 4-node model is given in Appendix A.2.

5.2.2.1 Model using 6-Node Quadratic Interface Elements

For 6-node interface element model, the average mesh size is 0.250 mm where the DCB body elements are modeled by 8-node quadrilateral elements. There are 2996 elements of which 380 interface elements exist. The element used for the body is *Element 27* [62] that is Plane Strain, 8-node Distorted Quadrilateral element that uses 3x3 Gaussian Integration [107] as shown in Figure 61. The properties of the body elements are considered as *orthotropic property* (Table 2) with plane strain.

Figure 61: Element 27, Plane Strain, 8-node Distorted Quadrilateral element. (“+”: Integration points, “□”: Nodes) [62]

The total number of nodes in the model is 9606 with two degrees of freedom. Hence, this yields $9606 \times 2 = 19212$ degrees of freedom. Also, in order to reduce the number of elements in the mesh, “bias” way of modeling is used as shown in Figure 62.

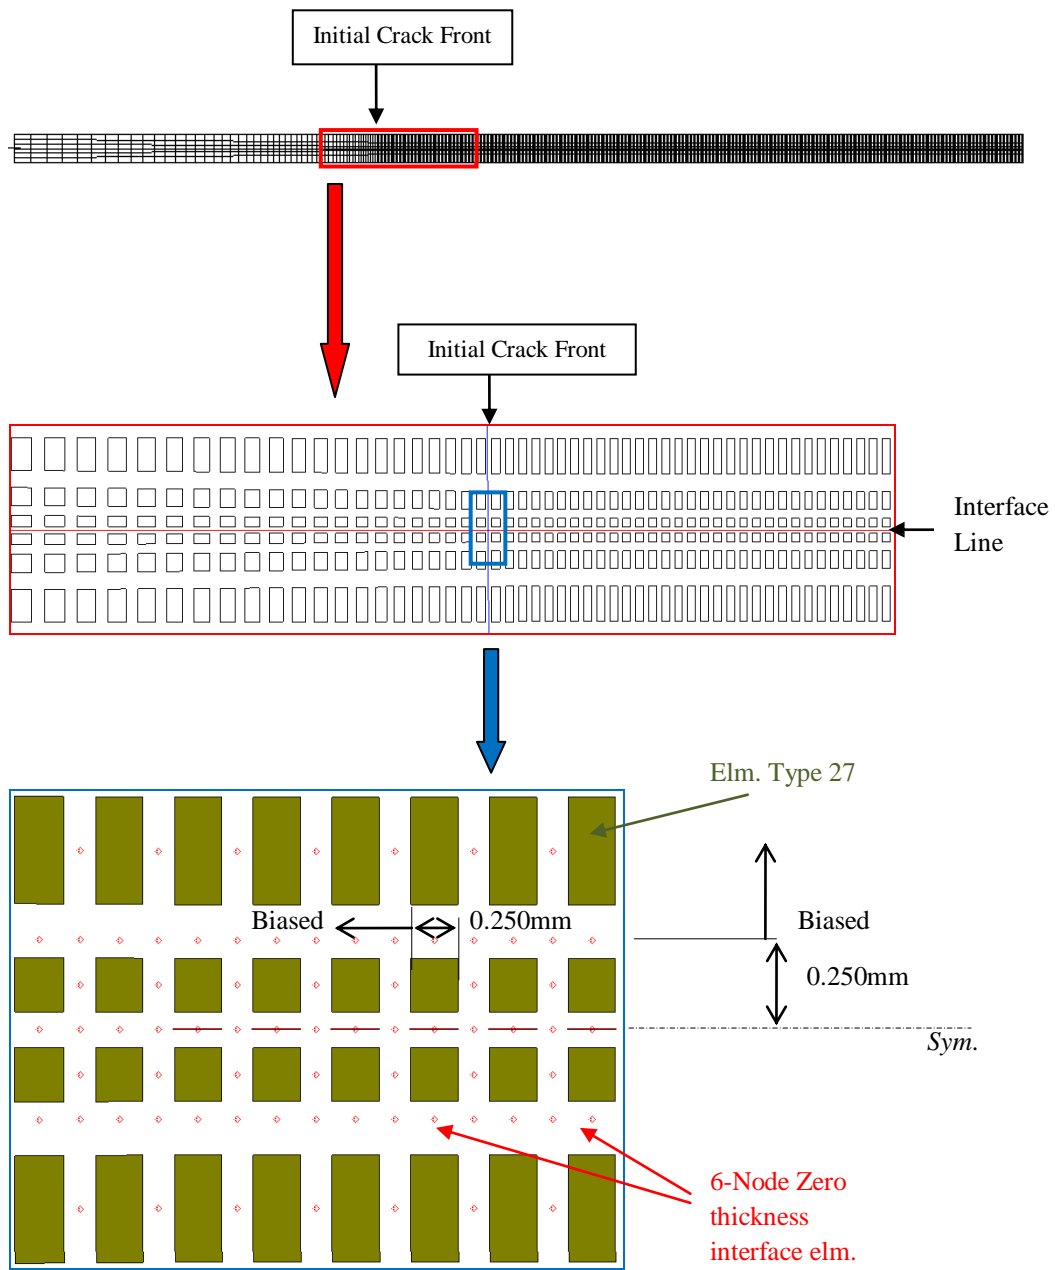

Figure 62: DCB model with zero thickness elements in model using 6-Node quadratic interface elements.

The bias feature of the mesh morphology should be in accordance with the aspect ratio, the ratio of element height to the element width, should not exceed 5 as suggested [61]. As a result, the model is both effective in terms of the total number of elements used and equally accurate concerning element dimensions.

5.2.2.2 Loading and Displacement Boundary Conditions

Since the displacement boundary conditions and the loading are irrespective to the mesh, they are summarized for both of the models in Figure 63. The tips of the arms are loaded to get rid of the mechanism error that may lead *excessive pivot ratios* [61]. To achieve this, the nodes at the middle on the right hand side surface are fixed in terms of translation in x and y and the rotation about z . These middle nodes are selected because of their location at the symmetry line.

Figure 63: Loading and the displacement boundary conditions.

The loading of the tips is *displacement* based. Since the apparatus of the DCB test is not modeled, the displacement input is exerted to the “tips” of the arms as shown in Figure 63. The profile with respect to *increment* is linearly increasing as shown in Figure 64.

Figure 64: Displacement vs. Increment input.

Note that, the unloading is not checked in this study. Therefore, the solution is finished when the loading curve is ended.

5.2.2.3 Solution Procedure and Parameters

The softening behavior of the cohesive zone elements makes the solution quite non-linear. Consequently, an appropriate nonlinear FEM procedure should be selected. In our study, there is no need to re-establish the latest coordinate configuration at each interface, after each iteration. Hence, the equilibrium can be expressed with the original undeformed state as the reference state. For this reason, *Total Lagrange Formulation* is used [61]. As a result, additional stiffness terms like the *initial stress matrix* are redundant. The preceding element stiffness matrix derivation is adequate.

For the non-linear solver, the spherical arc-length method is applied. Table 3 summarizes the parameters that are experienced as giving high convergence rates.

Table 3: Arc-Length solution parameters

First Fraction α_1	Max INC #	Max Iteration #	Desired recycle #	Max Fraction MAX(α_i)	C_{max}/C_1	Total Period	C_{min}/C_1	Arclength root procedure	Allowable time step cuts
0.001	50000	50	5	1	10.0000	1	0.001	1	5000

The above values are derived according to advancement of arc-length procedure. For instance, assume that for an increment, number of recycles is exceeded by reaching the value of 50 iterations. For this case, from Eqn. (102) in Appendix C, the new arc length would become;

$$\Delta l_0^{new} = \sqrt{\frac{5}{50}} \Delta l_0^{old} = 0.316 \Delta l_0^{old} \quad (86)$$

which shows the radius of diverged arc-length would become one-third for the next increment. As a result, the arc-length is decreased in a relatively fast way.

In addition to the arc-length parameters, the convergence is achieved according to the residual criterion. The *Tolerance* of the residual is taken as default value as 0.1. Note that, the details that are used for the above parameters can be found in Appendix C.

5.2.2.4 Analytical Solution

The benchmark test is compared with the analytically approximated solution in order to judge the accuracy of the study. From corrected beam theory and the definition of energy release rate, it is possible to find the analytical tip force-displacement curve as discussed before.

In order to draw the response curve, the *correction factor* χ_l should be found from Eqn. (5) as

$$\chi_l = \sqrt{\frac{150000}{11 \times 6000} \left[3 - 2 \left(\frac{618.79 \text{MPa}^{-1}}{1 + 618.79 \text{MPa}^{-1}} \right)^2 \right]} = 1.512 \quad (87)$$

The first equation of the piecewise response could be found by using Eqn. (4);

$$\Delta_i(P) = \frac{2P(55 \text{mm} + 1.512 \times 1.98 \text{mm})^3}{3 \times 150000 \times \frac{1.98^3 \text{mm} \times 20 \text{mm}}{12}} \rightarrow P_i(\Delta) = 14.923 \Delta \quad (88)$$

Similarly, for the failed region, the response can be reached by using Eqn. (7);

$$\Delta_f(P) = \frac{2(20 \text{mm} \times 150000 \text{MPa} \times \frac{1.98^3 \text{mm} \times 20 \text{mm}}{12} \times 0.352 \text{N/mm})^{3/2}}{3 \times 150000 \text{MPa} \times \frac{1.98^3 \text{mm} \times 20 \text{mm}}{12} \times P^2} = 17347.44 P^{-2} \Rightarrow \quad (89)$$

$$P_f(\Delta) = 131.71 \Delta^{-1/2}$$

In addition to the response, critical load could be calculated by using Eqn. (8);

$$P_c = \sqrt{\frac{20 \text{mm} \times 150000 \text{MPa} \times \frac{1.98^3 \text{mm} \times 20 \text{mm}}{12} \times 0.352 \text{N/mm}}{55 \text{mm} + 1.512 \times 1.98 \text{mm}}} = 63.7 \text{N}$$

And corresponding critical displacement can be found from Eqn. (89);

$$\Delta_c = 17347.44 \times (63.7)^{-2} = 4.27 \text{ mm}$$

As a result, the analytical response could be drawn from the above results;

Figure 65: Theoretical response

5.3 Verification of Interface Element Implementation

Since the interface elements are implemented into MSC MARC, they should be verified in order to ensure that they are working properly. Therefore, both the element formulations and the implementation are checked. For the formulation tests, since the CZM behavior is irrespective to the element type, only 6-node interface element is checked for this purpose.

The justification of formulation was performed by applying a complicated test loading on a “test element”. By a standalone model, this element is characterized with the cohesive zone formulations. Therefore, the element alone should respond as exact as the analytical bi-linear constitutive relationship. This test mainly checks the cohesive formulation. Moreover, the irreversibility is also checked in the element level.

For the element test, firstly, the Pure Mode – I loading was performed to a 6-node interface element using an interfacial allowable stress of 80 MPa and G_{IC} of 0.700 N/mm value with penalty stiffness of 10^6 N/mm³. The model and the boundary conditions are given in Figure 66. In words, *node 1* is *clamped*, and *node 2* and *node 3* are connected by *rollers*. Upper nodes are given displacement input with the same vector.

Figure 66: The model and the boundary conditions of standalone model for mode I test.

Prior to any run on the test element, the analytically critical displacement is supposed be calculated by using Eqn. (26) that gives

$$\delta_{ic} = \frac{2 \times 0.700 \text{ N/mm}}{80 \text{ MPa}} = 0.0175 \text{ mm}$$

Hence, the response of the element should reveal both the interfacial stress, and the maximum displacement within the interpenetration prevention ability. In scope of those items, Figure 67 shows the input and the response of the element.

(a)

(b)

Figure 67: Pure Mode check-run (b) input and (a) output.

It is seen from Figure 67 that from points *A* and *B*, the unloading curve successfully works. Also, the interpenetration ability works well if one considers the point *C*. Moreover, after reloading the curve to *B* and *D*, the “consumed” energy that spawns irreversibility is also working as expected. The numerical results, involving stresses and displacements, are almost exact with the analytical calculation. Hereby, it can be declared that the interface element behaves perfect for pure mode I.

Similarly, the same check is performed for the mixed-mode loading. The mixed-mode ratio β of 2.0 with 80 MPa of opening, 100 MPa of shearing interfacial strength and 0.7 N/mm of G_{IC} , 1.7 N/mm of G_{IIC} and $\alpha = 2.0$ for the quadratic failure are the parameters that is used for the mixed-mode loading test. The model and the boundary conditions are given in Figure 68Figure 66. In words, all lower nodes are *clamped*. Upper nodes are given displacement input with the same vector for both mode I and mode II directions.

Figure 68: The model and the boundary conditions of standalone model for mixed-mode test.

The corresponding analytical results can be found by using Eqn. (25);

$$\delta_{I_o} = \frac{80MPa}{100000N/mm^3} = 8 \times 10^{-4} mm \quad \text{and} \quad \delta_{II_o} = \frac{100MPa}{100000N/mm^3} = 10 \times 10^{-4} mm$$

Then using Eqn. (29), one may find the onset of delamination as follows;

$$\delta_o = 10 \times 10^{-4} mm \cdot 8 \times 10^{-4} mm \sqrt{\frac{1 + 2.0^2}{(10 \times 10^{-4} mm)^2 + (2.0 \cdot 8 \times 10^{-4} mm)^2}} = 9.48 \times 10^{-4} mm$$

Eqn. (33) gives the critical displacement;

$$\delta_c = \frac{2(1 + 2.0^2)}{9.48 \times 10^{-4} mm \cdot 10^5} \left[\left(\frac{1}{0.7} \right)^2 + \left(\frac{2.0^2}{1.7} \right)^2 \right]^{-1/2} = 0.038 mm$$

The corresponding pure mode failure parameters are finally calculated from Eqns.(28) and (30);

$$\tan(\theta) = 2.0 \Rightarrow \theta = 63.4^\circ$$

Yielding,

$$\delta_{Ic}^M = 0.038 mm \times \cos(63.4^\circ) = 0.017 mm$$

$$\delta_{IIc}^M = 0.038 mm \times \sin(63.4^\circ) = 0.034 mm$$

In the highlight of the above results, the response of the test element can be compared on Figure 69. Both the numerical results and the features like irreversibility, reloading, unloading and the interpenetration prevention, seem to be working properly if one investigates the results carefully. It is not necessary to continue for other mixed-mode ratios values because the mixed-mode ratio is nothing but a constituent of the formulations.

(a)

(b)

Figure 69: Mixed Mode (with $\beta = 2.0$) check run input and response

As a result, the cohesive formulation works perfect inside the element also in mixed-mode loading. Noting that, the stresses and displacements are irrelevant to the element type since the loading is introduced by a displacement input.

In terms of the element behavior, the formulation works successfully, the only remaining check is the response of the element in the whole FE model. As a result, one may check the element integration procedures that are formulated, like the element stiffness matrix and the internal force. To do that, for 40 MPa of interfacial stress, with $G_{IC} = 0.352 \text{ N/mm}$ and by a penalty stiffness of 10^6 N/mm^3 , the DCB model run described in the previous sections was performed. It should be noted that, although the original interfacial stress was 60 MPa, instead 40 MPa is used because of the guaranteed converged solutions as mentioned in the following paragraphs.

(a)

(b)

Figure 70: Stress distribution in vicinity of crack tip.

The response and the corresponding behavior of the element are summarized in Figure 70. The “wavy” traction profiles on the crack tip area seen Figure 73b, is in accordance with the behavior in Figure 37. Subsequently, it can be concluded that the behavior is nearly the same with the one given in Figure 37. The vital point is the crack tip traction behavior at the *critical load* point. As the traction becomes zero at the tip point, oscillations start at the global response.

Numerically, the critical load, limiting the uncontrolled delamination growth, was extracted from the MARC output file. The critical load P_c is 64.8 N and the critical displacement Δ_c is 4.65 mm. On the other hand, the theoretical critical load and the displacement are 63.7 N and 4.27 mm, respectively. The difference is quite small for both results. Note that, the difference in the critical load is more important than the difference in the critical displacement. This is due to the fact that the displacement is mainly driven by the beam theory assumption. On the other hand, the load is determined by the cohesive region.

However, after the critical load, the system does hardening instead of softening. In other words, on the load-displacement curve, as the displacement increases, the load increases after the critical point. This erroneous reaction is going to be discussed elaborately in the next chapter.

As a further study, the cohesive zone length can be extracted for the weakened interfacial trial as 1.25 mm (Figure 70). From the Eqn. (15), one may find the appropriate M value as follows;

$$l_{cz} = \left(11000MPa \frac{0.352N/mm}{(40MPa)^2} \right) (M) = 1.25mm \quad \Rightarrow \quad M \approx 0.52$$

This value is between Dugdale/Barenblatt and Rice/Falk values (Table 1). Therefore, our specific case should use $M = 0.52$ to define the cohesive zone length in plane strain assumption.

CHAPTER 6

RESULTS AND DISCUSSION

This study aimed to investigate CZM in terms of the latest advancements so as to reach the best CZM interface element. The criteria for the investigation are based on *accuracy* and *performance*. The performance of a feature is based on *convergence characteristics* and *solution time of the processor*. On the other hand, the *accuracy* criterion is based on the comparison with FEA results and the analytical approximations. In addition, the expected errors with the analytical approximate results are also referred to the same studies in literature.

The results and discussions of this study can be considered over the following items:

- I. Comparative Analysis of Unified Mode Approach vs. Separated Mode Approach
- II. Investigation of Artificial Modifications for Improving Convergence
 - a. Comparative Analysis of Models Using 6-Node Quadratic and 4-Node Linear Interface Elements
 - b. Effects of Decreasing Interfacial Strength and Penalty Stiffness
- III. Discussion about Convergence Performance

These issues are discussed in the following sections.

6.1 Comparative Analysis of Unified Mode Approach vs. Separated Mode Approach

The approaches of Unified Mode Approach (UMA) [3-4,12,68] and Separated Mode Approach (SMA) [1,2,21,59] have similar yet with unique characteristics. Therefore, their contrasts are discussed and investigated in terms of the accuracy and convergence performance.

Specifically, UMA uses direct application of initiation criterion of BK and it takes the total displacement as a damage parameter, whereas, SMA defines new damage parameter using pure mode displacements. Also, SMA does not involve BK criterion, instead; quadratic criterion is used. Actually, SMA uses power criterion due to the fact that the formulations in SMA is based on only

the pure mode parameters. Since BK criterion requires mixed-mode parameters, SMA is not suited for BK criterion. Moreover, another difference is the modification in which SMA approach adjusts the penalty stiffness values for each pure mode (Eqn. (100)). As mentioned in Appendix B, this modification is required for SMA in order to sustain the failure instant same for both of the shear modes and the opening mode. Otherwise, mode I and shear mode cannot be failed at the same instant; as a result, compatibility is not ensured.

Due to those differences, the tangent stiffness matrix becomes different between SMA and UMA. The tangent stiffness matrix is quite an important feature for the convergence performance if one recalls the arc-length method. To show the differences in the tangent stiffness matrix, the best way is to show the tangent stiffness matrices of both approaches, schematically.

Figure 71 illustrates a typical tangent stiffness matrix for UMA, schematically. The horizontal and the vertical axis are *Node i* and the degrees of freedoms, in which *Mode I* means the opening degree of freedom and *Mode II* implies shearing degrees of freedom (DOF). The orange boxes with *P* sign indicate that the stiffness in the box has the same sign with the stiffness value calculated by Eqn. (43). Obviously, *N* sign indicates the opposite. One may reveal that the orange boxes with *P* values form a *symmetry line* for the tangent stiffness matrix.

	: Non-Symmetric Terms
	: Positive terms
	: Negative Terms (N = -P)

Figure 71: Element Tangent Stiffness Matrix representation of UMA (for 6-node interface elm.)

As the mixed-mode ratio (Eqn. (11)) increases after initiation of the delamination, *local non-symmetric terms*, shown as pink boxes in Figure 71, emerge and increase, accordingly. The word “local” is used for naming the terms because these non-symmetric terms do not influence the overall symmetry of tangent stiffness matrix. On the other part, the word “non-symmetric” is used because

they are located in the pure mode – shearing mode DOF interaction term in the tangent stiffness matrix if only one *node-set* is considered (Eqn.(66)). The values of those terms are exemplified in Figure 72, in which the non-symmetric terms are calculated analytically by Eqn. (43). Note that, the element properties are same with the values given in Table 2 while the opening displacement is always kept as 0.0008 mm in order to sustain the interface element to be always in *softening region*. As a result, the tangent stiffness matrix is *symmetric*, as shown in Figure 71, and the evolution of the local non-symmetric terms is illustrated in Figure 72 for UMA.

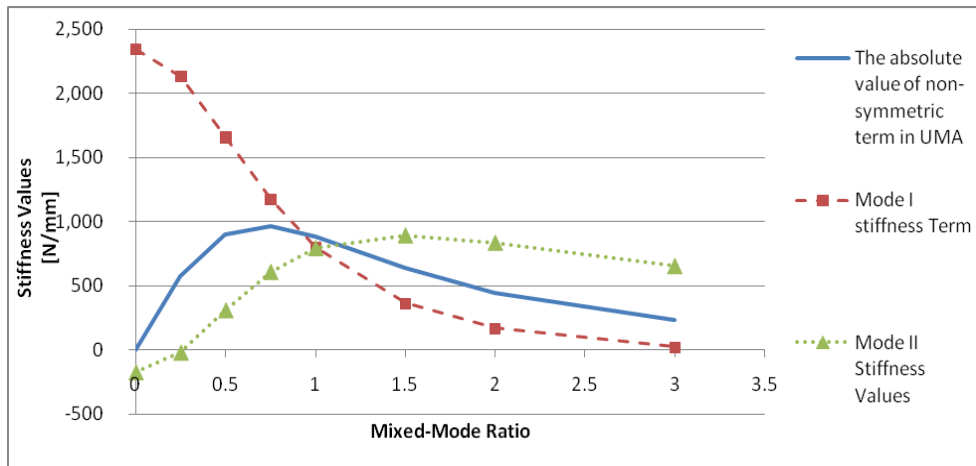

Figure 72: Stiffness values in tangent stiffness matrix in UMA approach. (Opening displacement is always kept as 0.0008 mm)

On the other hand, the story is different in the SMA. The modification given in Eqn. (100) yields variations among the non-symmetric terms in tangent stiffness matrix of SMA. This variation makes the tangent stiffness matrix of SMA non-symmetric as illustrated in Figure 73. However, un-symmetric tangent stiffness matrices are hard to be handled for FE solvers. For instance, MSC MARC2005r3 requires a special user indication in order to declare that the program should “expect” a non-symmetric stiffness matrix during the assembly. Hence, one needs to modify the solver program to deal with non-symmetric stiffness matrices.

--	--	---	--

Figure 73: Element Tangent Stiffness Matrix representation of SMA (for 6-node interface elm.)

Furthermore, the variation between a “dotted” pink box and a “clean” pink box is not negligible. For the same conditions used for Figure 72, the evolution of difference between adjacent “dotted” and a “clean” pink boxes are given in Figure 74. If one compares the numerical values of Figure 72 and Figure 74, it can be revealed that the difference in non-symmetric tangent stiffness matrix is not negligible. Therefore, this may yield a handicap for SMA in terms of convergence performance.

Figure 74: Absolute difference between a “dotted” pink box and a “clean” pink box for SMA.

For the accuracy point of view, The Tip Force – Displacement curves of the both approaches and the approximate analytical solution is given in Figure 75. For the accuracy point of view, both approaches result in nearly identical Tip force – displacement curve for the DCB test of our study (Table 2).

Figure 75: Tip force versus displacement response of UMA and SMA.

As a summary, it seems like the tangent stiffness matrices are different for the both of the approaches. Hence, the convergence performance and the overall performances might be different for mixed-mode cases.

6.2 Investigation of Artificial Modifications for Improving Convergence

In literature, researchers study for improving the convergence performance of the interface elements. In addition to the convergence, elapsed time for the solution of a run should also be considered. To cope with them, there are modifications for interface element material definitions and various types of interface elements [87-88,95]. As a broad discussion for them, the results of the below items are going to be discussed in this section.

6.2.1 Comparative Analysis of Models Using 6-Node Quadratic and 4-Node Linear Interface Elements

There are two runs involving identical arc-length and material parameters, yet with disparities only in the resulting meshes. The difference is morphological in the resulting meshes and emerged due to the elements used for modeling the body of the DCB. In 6-node interface elements, 8-node body elements are used as given in Chapter 5.2.2.1. On the other hand, 4-node interface element requires 4-node elements as presented in Appendix A. As a result, number of nodes used in the model is different. Moreover, the elements used in the interfaces are different in terms of the order of the shape function. Consequently, the comparison is performed; depending on convergence

performance, solution duration and response of the tip force – displacement curve (accuracy). It should be noted that the penalty stiffness is taken as 10^4 N/mm^3 instead of 10^6 N/mm^3 for all of the runs in order to guarantee the convergence.

The results of the runs reveal that the model using 6-node interface elements requires less time to finish the job as shown in Table 4. On the contrary, Table 4 stresses that the model using 4-node interface elements requires less number of increments to solve the model. Hence, even though the 6-node model requires more increments to finish the run, the time elapsed to finish the job is lower.

Table 4: Time and Increments to finish a job
(Performed in Intel Pentium Core2 6400 @ 2 x 2.13 GHz, 3 GB Ram)

	Time Elapsed	Inc. to Finish
4-node	28:58	347
6-node	18:14	411

Another performance criterion is the number of cycles required for achieving a converge at each increment. Figure 76 displays the graph of increment versus cycles, which is number of iterations to reach a converged point in an increment. Figure 76 reveals that 6-node element has more cycles in total, whereas, 4-node has localized cycles. After a while, the cycles in 4-node model abruptly drops. On the other hand, the number of cycles after the critical point is gradually decreasing the model of 6-node interface elements.

Figure 76: Increment vs. required cycles for converganc of increment for element types

Actually, the difference in Figure 76 can be expected when Figure 77 is examined thoroughly. It can be seen that the responses are nearly identical up to P_c . However, after that point, 4-node interface element model shows tougher and smoother characteristics. Whereas, 6-node one behaves in a typical oscillating response. However, since the response after the critical load are not correct - due to the unrealistic hardening -, a discussion about that region may not be correct.

Figure 77: Tip force vs. Displacement response for 4 node linear and 6 node quadratic interface elements

6.2.2 Effects of Decreasing Interfacial Strength and Penalty Stiffness

The most struggling issue of the CZM method is the possibility to face with low convergence rates. As suggested in [95] and [43], the number of elements that stay inside the cohesive zone should be high in order to get improvement in the convergence. On the contrary, as the number of elements is increased, the solution time for finishing the run is peaked. To cope with this conflict, some researchers [43,59,95,97] suggest to artificially reduce the interfacial strength to increase the cohesive zone (Eqn. (15)).

Therefore, by varying the interfacial strength as 10 MPa, 40 MPa and 60 MPa, trials with penalty stiffness of 10^6 N/mm³ are performed in order to see the impacts on the results. As pointed out by the Hallet et al. [43] that, unless the interfacial strength was decreased excessively, the resulting response would be similar. Actually, this is exactly the same case that we currently have (Figure 78).

Figure 78: Tip Force - Displacement response of various interfacial strengths

From Figure 78, it is seen that the trial with 60 MPa interfacial strength does not converge after P_c . On the other hand, 40 MPa case is converged after P_c . Finally, the interfacial strength of 10 MPa gives no convergence problem and without any high cyclic oscillations that shows better solution times. However, the result would be extremely soft, and hence; the solution was stopped manually.

The similar effect is observed, when the different penalty stiffness values is varied. As discussed before, penalty stiffness has a significant effect on convergence and the response of the structure as shown in Figure 47. Our study summarized trial runs in Figure 79 for 60 MPa interfacial strength on 6-node interface element model.

Figure 79: Sensitivity results of penalty stiffness values.

From Figure 79, although lower the penalty stiffness values greatly benefits the convergence rates, they would overshoot as in the 5×10^3 or yield “no softening” response like in 10^3 . Perhaps, it would be better to keep the penalty stiffness above 10^4 N/mm³ which is also a suggestion for some authors other than Turon et al. [96]. Moreover, the results are quite similar with the results shown in Figure 47.

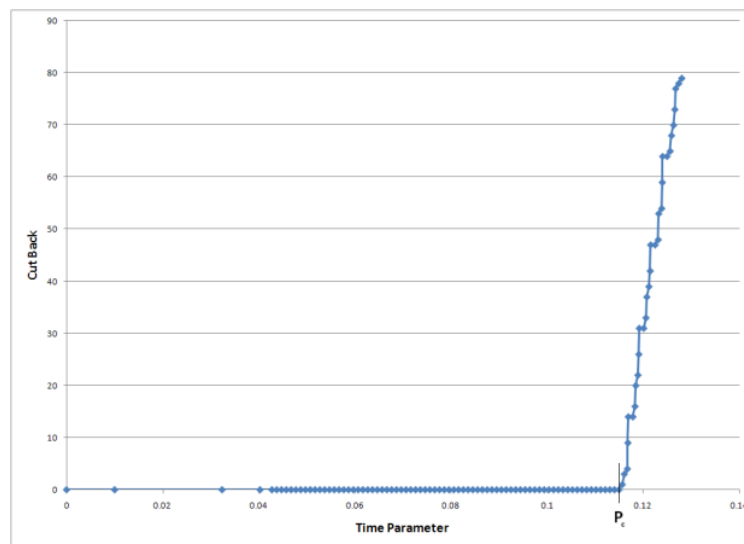

6.3 Discussion on Convergence Performance

During the study, convergence was one of the major problems encountered, especially after the critical loading attained. This can be identified easily in Figure 80 which shows time versus cycles and *cutbacks* required to get converged results for the model using 6-node interface elements.

Cutbacks happen in the cases where the number of iterations exceeds the limit that the user defines as a divergence criterion. In other words, a cutback is the phase where the radius of the arc-length is modified (Eqn. (86)). Therefore, the number of cutbacks in an increment can be a measure for criticizing the performance of a run. As seen from the Figure 80b, the number of cutbacks peaked after the critical load is achieved. Noting that, the cutbacks are given in cumulative way, such that, as the new cutbacks are formed, they are added to the previous cutbacks. From this point of view, it is expected to see linearly increasing cutbacks after the critical load. Therefore, the behaviors in the Figure 80a and Figure 80b can be expected.

(a)

(b)

Figure 80: Cycle and Cutback segregation throughout the solution.

The number of cycles is also a measure for considering the convergence performance. It can be seen from Figure 80a that after the critical load achieved, the number of cycles to reach converged points is peaked and remained same.

Therefore, from the cutback vs. time parameter graph (Figure 80b) and the cycle vs. time parameter graph (Figure 80a), it can be summarized that after critical load achieved, the convergence

performance is lowered and retained with the “lowered value” throughout the remaining analysis. Hence, it could be said that there are two regions in terms of convergence during the solution; “before the critical load” and “after the critical load”. Also, these two regions have negligible variations inside.

CHAPTER 7

CONCLUSIONS

Cohesive Zone Method (CZM) is widely investigated, and the study is mainly focused on finite element application of the method. In fact, the motivation is to achieve a CZM interface element; having high accuracy, high convergence characteristics, and consequently; high overall performance. Our study is aimed to be a preliminary study for this objective.

The investigation about CZM is started with a discussion about the theory in comparative way among the other methods of delamination propagation. Especially, a broad theoretically comparative discussion between Virtual Crack Closure Technique (VCCT) and CZM is given. It is concluded that CZM is more efficient and more capable than VCCT. Besides, the selected numerical solution scheme; the arc-length method is also re-derived from well known Newton-Raphson method. In parallel, the convergence issue and the importance of the numerical solution scheme is discussed.

The two main approaches for CZM formulations are categorized as; Unified Mode Method (UMA) and Separated Mode Approach (SMA). Accordingly, they are compared and contrasted numerically in a finite element model of DCB test. On the other hand, the differences in tangent stiffness matrices of the two approaches are brought out, theoretically. The formation of non-symmetric tangent stiffness matrices for SMA is revealed in high mixed-mode ratios. Next, the artificial modifications improving convergence performance; using 6-node quadratic interface elements instead of 4-node linear interface elements, reducing the penalty stiffness and the interfacial strength are investigated.

It is observed that the approaches of UMA and SMA result in identical accuracy for the DCB test model [70]. However, the key point for the convergence performance is the element tangent stiffness matrix. At this point, it is theoretically shown that SMA is prone to form non-symmetric tangent stiffness matrices in high mixed-mode ratios, β . Moreover, it is also shown that the non-symmetric tangent stiffness matrix of SMA is in considerable values and hence; it is suggested taking this effect into account by applying mixed-mode loading cases. It is highlighted that handling of non-symmetric stiffness matrices can make SMA a cumbersome approach. For the tip force-displacement curve of the DCB model, after the critical point is reached, the different oscillatory

behaviors are observed for each approach. However, since the response on that region is not correct due to the hardening behavior, such a discussion about oscillatory response is not applicable.

The models, using interface elements of 4-node linear or 6-node quadratic elements, were compared in terms of convergence rates, overall performance and accuracy. The results show that the model using 4-node interface element requires fewer increments, yet with longer solution duration to finish a job. This contradictory result could be occurred because of two differences between two models; the first is the number of interface elements and secondly, the morphological differences.

Low number of increments to finish a job can be assumed to mean a better convergence rate. Therefore, the model using 4-node interface elements can be considered the one having the best convergence rate. This result is happened possibly due to the fact that, the total number of 4-node interface elements is twice the number of 6-node interface elements used in their corresponding models. In other words, there are two times more interface elements used in the model with 4-node interface elements. Recalling from the Section 5.2.2.1 and Appendix A, the models of 4-node and 6-node interface elements are somehow “correlated” by having the same aspect ratios of the elements. Consequently, using twice number of interface elements might have improved the convergence rate of the model using 4-node interface element, even though the order of the 4-node linear interface element is lower than the 6-node quadratic interface element.

On the other part, the model using 6-node interface elements requires less time to finish the job. The reason might be due to the requirement of an additional node to “convert” one 8-node body element into four 4-node body elements. This phenomenon is best illustrated in Figure 81. The additional node – displayed as shaded in the middle of the Figure 81– is required to put four 4-node quad body elements to fill the volume of one 8-node body element. Actually, this is the reason of the morphological difference between the two models. Consequently, the model using 4-node interface elements has more nodes, and hence; yields more degrees of freedom in the assembled stiffness matrix. In our case, there is 27.2% (exactly 5232) more degrees of freedom in the assembled stiffness matrix of the model using 4-node linear interface elements. Consequently, more degrees of freedom might result in the higher computational duration.

Figure 81: 8-node element “hatches” four 4-node elements with one additional node emerged at the middle.

Next, the weakening of interfacial strength and lowering the penalty stiffness are examined so as to find appropriate modifications leading to an effective interface element. By direct investigation of the results, one may declare that they give quite parallel results regarding to the similar studies performed in literature [12,43,59,72,96].

A decrease in interfacial strength gives better convergence rates and yet, still accurate results if the decrease is “under control”. Otherwise, after a certain value, it is observed that the model starts to give inaccurate results. For the instance of the DCB test performed by Morais et al. [70], it is obtained that an interfacial strength of 10 MPa results in excessively soft response (Figure 78). It seems like 40 MPa gives good results since the critical load is identical to the one obtained for the actual 60 MPa case (Figure 78). It should be noted that the weakening of the interfacial strength may give over-estimated allowable for delamination onset [39]. However, since our study does not analyze initiation of delamination cracks, possible influences of weakening the interfacial strength on the delamination initiation are automatically skipped.

Likely observed for the weakening of the interfacial strength, decrease in the penalty stiffness has a similar effect. In fact, this is the reason why they are considered in the same section in our study. For the penalty stiffness of $5 \times 10^3 \text{ N/mm}^3$, the result spawns overshoot critical load whereas, the others above 10^4 N/mm^3 highlights identical critical loads as seen for all of the models (the DCB test performed by Morais et al. [70]). An excessively soft penalty stiffness of 10^3 N/mm^3 behaves like the interfacial strength of 10 MPa with inaccurate and excessively softened results in our model. Perhaps, it would be convenient to use a penalty stiffness of 10^4 N/mm^3 or 40 MPa of interfacial strength to get rid of the fine mesh requirement in this test. Namely, it is suggested that by using lower penalty stiffness and weaker interfaces, it would not need to model with cumbersome fine meshes. In fact, this conclusion is agreed by the literature [12,43,59,72,96].

During the study, one of the most challenging points experienced is divergence. It is experienced that MARC 2005r3 has awful characteristics in terms of convergence ability. First of all, MARC does not

have the Modified Arc-Length Method which is specialized in dealing with sharp snap backs [18,61]. This modified method has a better root selection scheme that also considers residuals to catch snap backs instead of only checking the minimum angle [18]. Therefore, the Arc-Length Method inside MARC 2005r3 is old-fashioned. Moreover, MSC MARC 2005r3 does not have a procedure like, *viscous regularization* [24,27], which improves convergence by “damping” the tangent stiffness matrices of softening constitutive relationships. Therefore, although the suggestions of Turon et al. [96] were followed during our study, the convergence still became a problem.

As a result of numerical results of the finite element analysis and the verifications, it can be concluded that, there is no problem in embedding the CZM formulation. Hence, the results are satisfactory and adequate to declare that the formulations have been successfully implanted into MSC MARC 2005r3. Also, all of the foregoing runs show the same and the correct critical force and critical displacement values. However, only the overall response of the structure after the critical load, P_c , is not correct. In our study, after the critical load reached, there is no softening of the structure, which is supposed to cause “uncontrolled” crack propagation. Since the critical load is checked in terms of detailed cohesive zone analysis by the interface element traction-displacement evolution curves, the results are reasonable. The error could be emerged from an error accumulation during the numerical solution scheme. Therefore, a further investigation with lower residual tolerances is required in the region after critical loading. Actually, this is the only deficiency of our study that requires further investigation.

Additionally, widely used commercial program, like ABAQUS [24], could be used in order to see whether the error is occurred because of the MSC MARC 2005r3. This is reasonable because the “communication” between the user-subroutine and the solver, or any other programming error might be the problem. Moreover, the usage of user-subroutines in literature is more common for ABAQUS. In brief, the mitigation could be to change the commercial FEA program and check possible programming problems.

For the last but not the least, this study needs to be developed further to enhance the convergence issue, and understanding the over-stiff response after critical load it needs the application of more tests like ENF, MMB to acquire more knowledge to further clarify the above issues. Moreover, implementing the interface elements into other commercial programs, possible problems emerged by MSC MARC2005r3 would diminish. In either way, the findings in this study promise many aspects of fields to investigate more in deeply.

CHAPTER 8

FUTURE WORKS

The study definitely requires solving the erroneous response after the critical load is achieved. The same formulations are going to be implemented into ABAQUS which is widely used by researchers. If the problem still exists, than by comparing the inherent interface elements already implemented into ABAQUS, it would yield a chance to understand any error output of the developed interface element.

It seems like the global effect of utilization of interface elements could be studied more deeply. Generally, the general view of a method is overlooked by researchers. Therefore, it would be better to study on the global performance of a model in the scope of selecting the appropriate interface element. In addition, the differences of the approaches concerned in our study could be investigated in terms of performance characteristics by set of MMB test models. As a result, the effects of non-symmetric tangent stiffness matrices for SMA could be revealed.

For a longer term, nowadays *Nano-Composite* structures are modeled by constitutive relationships in finite element models. Representative elements are being developed on this field. The experience in this thesis might be continued to high performance develop representative elements for the field of nano-materials like nano-composites.

APPENDIX A

FOUR NODE LINEAR INTERFACE ELEMENT FORMULATION AND MODEL

A.1 The Element Formulation

Although MARC has an inherent 4-node plain strain linear interface element definition (*Element 186* [62]), it would be better to construct our own 4-node plain strain element similarly done for 6-node element in the Chapter 5.1.

The 4-node plain strain linear interface element has 2 integration points as shown in the Figure 82. The element acts as linear line element which possesses interpolation equation of generalized linear formulation, can be given as [107];

$$\phi(\xi) = a_0 + a_1\xi \tag{90}$$

Figure 82: (a) 4-node linear plain strain interface element details (b) Node-set definitions

The shape functions should have same degree given in Eqn. (91). By obtaining zero in the node set s_2 , the candidate shape function for node set s_1 is;

$$N_1(\xi) = C(\xi - 1) \quad (91)$$

In order to give unity at node set s_I ($\xi = -1$), the constant C can be found as;

$$N_1(-1) = C(-1-1) = 1 \quad \Rightarrow \quad C = -\frac{1}{2} \quad (92)$$

Similarly, the second shape function could be done accordingly. Hence, the shape function for node 1 and 2 could be summarized as;

$$N_1(\xi) = \frac{1}{2}(\xi - 1) \quad , \quad N_2(\xi) = \frac{1}{2}(\xi + 1) \quad (93)$$

For the element kinematics, a similar rotational formulation could be defined by the same AB line defined for 6-node quadratic interface element;

$$A = \left(\frac{X_4 + X_1}{2}, \frac{Y_4 + Y_1}{2} \right) \quad , \quad B = \left(\frac{X_3 + X_2}{2}, \frac{Y_3 + Y_2}{2} \right) \quad (94)$$

where the X_i and Y_i shows the coordinates of the nodes. The angle of misalignment can be defined as follows;

$$\theta = \tan^{-1} \left(\frac{Y_2 + Y_3 - Y_1 - Y_4}{X_2 + X_3 - X_1 - X_4} \right) \quad , \quad 0 < \theta \leq 90^\circ \quad (95)$$

The *global relative displacement to global nodal displacement matrix* \mathbf{B} is similar to the one derived in 6-node, except the dimensions of the matrix is 2x8 with N_1 and N_2 defined in Eqn. (93).

For the element integration, the determinant of Jacobian matrix is parallel with the 6-node one as follows;

$$Det(J) = l/2 = \frac{\sqrt{(X_2 + X_3 - X_1 - X_4)^2 + (Y_2 + Y_3 - Y_1 - Y_4)^2}}{4} \quad (96)$$

Following it the numerical integration scheme would be Newton-Cotes with 2 integration points with, $H_1 = H_2 = l$ while and $\zeta_1 = -l$, $\zeta_2 = l$ referring to Eqn. (85).

A.2 Model Using 4-Node Linear Interface Elements

The average mesh size is 0.125 mm where the DCB elements are modeled by four node quadrilateral elements. There are 11224 elements of which 760 interface elements exist. Body elements are *Element 11*, which is called *arbitrary quadrilateral plane strain element* [62] using *2x2 Gaussian Integration* [107]. The number of nodes in the model is 12222 that cover the two degrees of freedom u and v as shown in Figure 83. Hence, roughly the degrees of freedom are $12222 \times 2 = 24444$.

Figure 83: Element 11, Arbitrary Quadrilateral Plane Strain Element (“+”: Integration points, “□”: Nodes) [62].

In order to reduce the number of elements in the mesh, “bias” way of modeling is used as shown in the below as done for the 6-node case. Similarly, the bias feature is accorded with the aspect ratio without exceeded above 5 as suggested [61].

APPENDIX B

CONSTITUTIVE RELATIONSHIP OF SEPARATED MODE APPROACH

Also, one of the objectives of our study is to compare and contrast the differences between the studies of Separated Mode Approach and Unified Mode Approach. Also, Separated Mode Approach (SMA) [1,16,59,72] has unique advancements. Therefore, such differences are mentioned in this section.

The initial difference is the definition of the damage evolution by proposing a new *damage parameter* γ as follows [1];

$$\gamma = \left[\left(\frac{\langle \delta_I \rangle}{\delta_{Io}} \right)^\alpha + \left(\frac{|\delta_2|}{\delta_{IIo}} \right)^\alpha \right]^{1/\alpha} - 1 \quad (97)$$

Analogy with Eqn. (35), the damage evolution can be controlled by [1]

$$\gamma^{\max}(t) = \max_{\tau \leq t} \gamma(\tau) \quad (98)$$

The approach of SMA does not use the delamination onset criterion like *elliptical law*. As a result, the most unique characteristic of this approach is that there is no such a parameter of total displacement, δ . In other words, whole delamination analysis is performed in displacements in pure modes and it indirectly uses the mixed-mode criterion via those pure mode displacements. Hence, Chen and New [16] proposed a non dimensional damage parameter λ to define the state of the damage by using only pure mode displacements and critical displacements, which is defined as;

$$\lambda = \sqrt{\left(\frac{\delta_I}{\delta_{Ic}} \right)^2 + \left(\frac{\delta_2}{\delta_{IIc}} \right)^2} \quad (99)$$

in which λ becomes unity when the full delamination occurs, whereas, it becomes zero for no damage.

Actually, the definition of damage in terms of pure modes causes delamination failure at different instants for each pure mode failure. This issue was illustrated by Pinho et al. [71] in Figure 84. One may realize from the figure that the original constitutive law (“Before Compatibility”) is not “consistent” in terms of the instant when the full damage attained.

Figure 84: Compatibility of Mode I and Mode II [71].

In order to deal with this problem, Alfano and Crisfield [59] proposed to redefine the delamination onset displacement in Mode II for the compatibility requirement as follows;

$$\frac{\delta_{Ic}}{\delta_{Io}} = \frac{\delta_{IIc}}{\delta_{IIo}} \quad \rightarrow \quad \delta_{IIo} = \frac{\delta_{Io}}{\delta_{Ic}} \delta_{IIc} \quad (100)$$

In fact, this definition is indirectly adjusting the penalty stiffness in Mode II which does not yield a problem since the redefinition is in the orders below 10 [59]. The penalty stiffness in mode II for a stable interfacial strength in mode II can be found from Eqn. (25) and Eqn. (100) as;

$$E0_{II} = t_{1c} \frac{\delta_{1c}}{\delta_{11c} \delta_{1o}} \quad (101)$$

Therefore, the above adjustment of Mode II penalty stiffness would result in a compatible constitute relationship for SMA as shown in Figure 84 by “Current SMA”.

APPENDIX C

USER CONTROL IN ARC-LENGTH AND NUMERICAL SOLUTION IN MARC

MSC MARC grants some variables to the users in order to control the arc-length method. Since the convergence is an important issue, this section is dedicated for giving the details of the arc-length parameters that are adjusted to reach converged solutions.

In subsequent steps the arc-length can be reduced or increased at the start of a new load step depending on the number of iterations in the previous step, I_0 . This number of iterations is compared with the desired number of iterations, I_d which is typically set to 3 or 5 [61]. The new arc-length is then given by [61]

$$(\Delta l_0^{new})^2 = \frac{I_d}{I_0} (\Delta l_0^{pre})^2 \quad (102)$$

Hence, the way of convergence is considered by evaluating the previous increments' iteration to consider the new candidate arc length. On the other hand, the convergence could not be attained for the cases where the maximum number of iterations defined by the user in the AUTO INCREMENT card of the MARC being exceeded.

In addition to Eqn. (102), MARC has two other controls [61] given by

$$MAX < \frac{\Delta l_i^n}{\Delta l_0^1} < MIN \quad (103)$$

Therefore, the MAX and MIN values could be set in order to limit the maximum enlargement or the minimum reduction in the arc-length. In addition to this, maximum load multiplier can also be set [61].

And finally, the residual correction shape is controlled via the absolute or relative type of check. Since absolute value of the residual is not always the same, best way to control the convergence is by setting the relative residual force margin with respect to the reaction force [61] as

$$\frac{\|g_i^n\|}{\|F_{reaction}\|} < Tolerance \quad (104)$$

The above equation can also be written according for moments, yet, moments need not to be checked in our study. Therefore, the “Tolerance” value is only the tolerance for the forces.

CURRICULUM VITAE

PERSONAL INFORMATION

Surname, Name: Gözlüklü, Burak
Nationality: Turkish (TC)
Date and Place of Birth: 14 August 1983, Ankara
Marital Status: Single
Phone: +90 0532 250 00 96
Email: bgozluklu@tai.com.tr

EDUCATION

Degree	Institution	Year of Graduation	C.GPa
MS	METU Mechanical Engineering	2009	3.50
BS	METU Mechanical Engineering	2006	3.18
Minor	METU Metallurgical and Materials Engineering	2006	2.50

WORK EXPERIENCE

Year	Place	Enrollment	Project, Position
2007-Present	TUSAŞ-Turkish Aerospace Industries Inc. (TAD)	Stress Analysis Engineer	Airbus A350 XWB “Ailerons”, Outer Aileron Stress Analysis Responsible Airbus A350 XWB “Ailerons”, Fatigue Analysis Responsible EU 6th Framework Programme: ALCAS, Stress Analysis Responsible
2006-2007	Aero-Limak Inc.	Product Engineer	ALGA – Automated Advanced Fuselage Analysis Program, Program Developer
2005-2006	METU	(Volunteer)	Formula-G Solar Powered Car Race, Project, Stress Analysis Responsible.

FOREIGN LANGUAGES

Advanced English (TOEFL 2009 iBT Score: 100/120)

SOCIAL

Martial Arts (having EBMAS-Martial Arts Schools, Wing Tsun Kung-Fu Instructor Certificate)
Boxing
Escrima (Filipino Martial Arts)
Brazilian Jiu-Jitsu (Brazilian Martial Arts)
Scuba Diving (having CMAS One Star Scuba Diver License)
Interest in Quantum Physics, Astro-Physics and Philosophy
