AB – INITIO DEVELOPMENT OF Ca-Ni BASED ALLOYS FOR METAL HYDRIDE BATTERIES

A THESIS SUBMITTED TO THE GRADUATE SCHOOL OF NATURAL AND APPLIED SCIENCES OF MIDDLE EAST TECHNICAL UNIVERSITY

BY

ORKUN MUĞAN

IN PARTIAL FULFILLMENT OF THE REQUIREMENTS FOR THE DEGREE OF MASTER OF SCIENCE IN METALLURGICAL AND MATERIALS ENGINEERING

SEPTEMBER 2012

Approval of the thesis:

AB – INITIO DEVELOPMENT OF Ca-Ni AND La-Ni BASED ALLOYS FOR METAL HYDRIDE BATTERIES

submitted by **ORKUN MUĞAN** in partial fulfillment of the requirements for the degree of **Master of Science in Metallurgical and Materials Engineering Department, Middle East Technical University** by,

Prof. Dr. Canan Özgen Dean, Graduate School of **Natural and Applied Sciences**

Prof. Dr. Hakan Gür Head of Department, **Metallurgical and Materials Engineering**

Prof. Dr. M. Kadri Aydınol Supervisor, **Metallurgical and Materials Eng. Dept., METU**

Examining Committee Members:

Prof. Dr. Tayfur Öztürk Department of Metallurgical and Materials Engineering, METU

Prof. Dr. M. Kadri Aydınol Department of Metallurgical and Materials Engineering, METU

Assoc. Prof. Dr. Zafer Evis Department of Engineering Sciences, METU

Assist. Prof. Dr. Y. Eren Kalay Department of Metallurgical and Materials Engineering, METU

Assoc Prof. Dr. Yener Kuru Department of Materials Science and Engineering, Akdeniz University

Date: 11.09.2012

I hereby declare that all information in this document has been obtained and presented in accordance with academic rules and ethical conduct. I also declare that, as required by these rules and conduct, I have fully cited and referenced all material and results that are not original to this work.

ABSTRACT

AB – INITIO DEVELOPMENT OF Ca-NI BASED ALLOYS FOR METAL HYDRIDE BATTERIES

MUĞAN, Orkun

Master of Science, Department of Metallurgical and Materials Engineering

Supervisor: Prof. Dr. M. Kadri AYDINOL

September 2012, 53 pages

Ni-MH battery today is one of the most widely used secondary battery type because of its properties like secure use at high voltages, excellent thermal properties and consisting of environmentally acceptable materials. LaNi₅, as an anode material, is the dominant commercial active material for the Ni-MH battery industry. CaNi₅, belonging to same crystal structure, is an alternative for LaNi₅, due to higher hydrogen storage capacity, higher theoretical discharge capacity, light weight and low cost. However, low cycle life is the main restriction for the use of CaNi₅. In this study, effects of alloying was studied using an ab initio pseudo potential method. In this regard, formation energies of the CaNi₅ compounds having different alloying elements were calculated for the understanding of the effect of the alloying element on the stability of the compound. It was found that, all lanthanides and actinides and early transition metals (Sc, Y, Zr, Hf) replacing Ca and early transition metals (Sc, Ti, Zr, Hf) plus elements like Al, Si, P, Ge, Zn, Sn and Sb replacing Ni, decrease the formation energy of CaNi₅. Lower formation energy, compared to the pure compound, increases the stability which could improve the cyclic durability of CaNi₅ to be used as an anode in Ni-MH batteries. In addition, in order to investigate effects of alloying on Ca diffusion in CaNi5, activation energies of Ca diffusion for different alloys were calculated by Nudged Elastic Band method (NEB) method.

METAL HİDRİD BATARYALAR İÇİN Ca-Ni ALAŞIMLARININ AB INITIO İLE GELİŞTİRİLMESİ

MUĞAN, Orkun

Yüksek Lisans, Metalurji ve Malzeme Mühendisliği Bölümü

Tez Yöneticisi: Prof. Dr. M. Kadri AYDINOL

Eylül 2012, 53 sayfa

Günümüzde, kullanım alanlarının geniş olması yüksek voltajlarda bile güvenli oluşları ve çevre dostu olmaları nedeniyle, Nikel – Metal Hidrid bataryaları en yaygın olarak kullanılan ikincil bataryalardan biridir. LaNi₅, Nikel – Metal Hidrid batarya endüstrisinde anot malzemesi olarak en fazla kullanılan aktif malzemedir. LaNi₅ ile aynı kristal yapıda olan CaNi₅ ise daha fazla hidrojen depolama kapasitesi, daha fazla deşarj kapasitesi, daha hafif ve ucuz oluşundan dolayı LaNi₅'in en büyük alternatifi konumundadır. Ancak çeviri ömrünün çok kısa olmasından dolayı bataryalarda aktif anot malzemesi olarak kullanılamamaktadır. Bu bağlamda, yapılan teorik çalışmada alaşımlı bileşiklerin ve hidrürlerinin formasyon enerjileri temel prensipler yöntemiyle hesap edilmiştir. Buna ek olarak NEB (nugged elastic band) yöntemiyle Ca atomunun yapı içindeki yayınım aktivasyon enerjileri hesap edilmiştir. Elde edilen sonuçlara göre, nadir toprak elementlerinin Ca yerine kullanılarak alaşımlandırılma yapıldığında sistemin kararlılığını arttırdığını görmekteyiz. Ayrıca bazı geçiş elementlerinin de (Hf, Sc, Y, Zr) Ca yerine kullanıldığında sistemin enerjisini düşürdüğü görülmüştür. Ni yerine yapılan alaşımlandırmalarda ise özellikle Al, Si, Ge ve P' nin çok etkili olduğu Sb, Sn, Sc, Zn, Zr, Hf ve Ti gibi elementlerin ise kısmen yararlı etki yaratacağı tespit edilmiştir.

Anahtar Kelimeler: Ni-MH bataryalar, ab initio çalışmaları, CaNi₅, LaNi₅

ACKNOWLEDGEMENTS

I would like to thank my supervisor, Prof. Dr. Kadri Aydınol, whom helped me a lot during my master thesis. I also thank my father Azer Muğan, my mother Beyza Muğan and my sister Güliz Muğan Akıncı whom supported me with their ultimate kindness.

I owe my deepest gratitude to my lab-mates and dearest friends Berke Öksüz, Ali Arda Özkenter and Uğur Akyıldız for their infinite support, patience and kindness.

This study was supported by The Scientific and Technological Research Council of Turkey (Tübitak) Grant No: 109M692 and the numerical calculations were performed at the ULAKBIM High Performance Computing Center in TUBITAK, within the TR-Grid e-Infrastructure project.

CHAPTER 1

INTRODUCTION

New technological developments on electronic devices increase the importance of the energy storage. Smaller and more efficient electrical and electronic systems make the batteries key product for portable applications for example cell phones, cameras, vehicles, etc. Energy can be stored by many ways but secondary batteries are more economical because of their rechargeable characteristic and they have been used since middle of 1800. First battery type was lead batteries developed by Gaston Plenté in 1859. About in 1950s, first alkaline electrolyte using Ni-Cd batteries were produced [1]. These technological developments were followed by development of different battery types. Today, there are many secondary battery types such as lead - acid batteries, nickel - cadmium batteries (Ni-Cd batteries), nickel - metal hydride batteries (Ni-MH batteries) and lithium-ion batteries (Li-ion batteries). However, Ni – MH batteries have some advantages over other secondary battery types such as excellent thermal properties, secure use at high voltages, consisting environmentally acceptable and recyclable materials and safety in charge, discharge characteristics [2]. In this manner, since the developments in the late 1980s, popularity of Ni-MH battery have increased and used in many portable electrical devices such as laptop computers, cell phones, cassette players, toys etc [3]. Properties of a Ni - MH battery are given on following table.

	Ni – MH battery
Nominal Voltage	1.2 V
Specific Energy	75 Wh/kg
Energy Density	240 Wh/L
Operating Temperature	-20 to 50 ⁰ C
Cycle Life	300-600
Discharge Profile	Flat

Table 1. Common	properties	of a Ni -	MH battery	/ [2]
-----------------	------------	-----------	------------	-------

Chemistry of a Ni – MH battery have some similarities with the Ni - Cd battery. As in Ni – Cd battery, positive electrode is nickel oxyhydroxide (NiOOH) in charged state. On the other hand, differently from Ni – Cd battery, hydrogen is stored in negative electrode as a metal hydride at charged state. Charge and discharge reactions of Ni – MH battery can be seen on following formulas [2].

Positive electrode:

$$NiOOH + H_2O + e^{-} \xrightarrow{discharge}_{charge} Ni(OH)_2 + (OH)^{-}$$
(1)

Negative electrode:

$$MH_{x} + OH^{-} \qquad \xrightarrow{\text{discharge}} MH_{x-1} + H_{2}O + e^{-}$$
(2)

As can be seen, in negative electrode, hydrogen is absorbed and desorbed during charging and discharging. Therefore, hydrogen storage should be reversible. In this context, intermetalics are used as negative electrode materials in Ni – MH battery. The most important intermetallic groups are tabulated on Table 2. These intermetallic groups mostly determine capacity, cycle life and electrochemical characteristic of Ni – MH battery. AB₅ is the most widely used intermetallic group in Ni – MH batteries because it has some advantages over other intermetallic groups such as better cycling properties, better long term cycling stability and higher volumetric storage density [4]. On the other hand, intermetallics on this group can lose their reversible hydrogen storage capacity.

Intermetallic Compound	Prototype	Hydrides
AB ₅	LaNi₅	LaNi₅H ₆
AB ₂	ZrV ₂	ZrV ₂ H _{5.5}
AB ₃	CeNi ₃	CeNi ₃ H ₄
A ₂ B ₇	Th ₂ Fe ₇	Th ₂ Fe ₇ H ₃
AB	FeTi	FeTiH ₂
A ₂ B	NiMa ₂	Ma₂NiH₄

Table 2. The most important hydride-forming intermetallic groups, prototypes and their hydrides.

LaNi₅, belonging to CaCu₅ crystal structure, is the most widely used commercial active materials of this group. However, in order to increase cycle life and reduce the cost, LaNi₅ is used as an alloy with MmNi_{3.55}Mn_{0.4}Al_{0.3}Co_{0.75} composition where Mm represents a mixture of rare earth elements [5]. Unfortunately, since La is a relatively expensive rare earth element, other alternatives for LaNi₅ are searched because according the researches, 45 % of the total cost of a Ni – MH battery belongs to negative electrode of the battery [6]. In this manner, CaNi₅ turns out to be an important alternative. CaNi₅ has higher specific hydrogen storage capacity than LaNi₅. Also, theoretical capacity of CaNi₅ is 482 mAhg⁻¹, while it is 372 mAhg⁻¹ for LaNi₅ [7] Therefore, CaNi₅ has a very important potential to be an alternative for LaNi₅. However, very

low cycle life of CaNi₅ limits its use in commercial applications. Low cycle life is used to be the problem of LaNi₅ too, but with proper alloying additions it was solved to a certain extent. Same approach can also be used to solve the cycle life problem of CaNi₅. Therefore, in this study, the effects of different alloying elements on the stability of the CaNi₅ compound were investigated because thermodynamic stability may be one of the reasons of low cycle life. In this manner, 48 different alloying elements were selected from the periodic table and the formation energy of the Ca-Ni based alloys were calculated using first principle theories. In addition, in literature it is seen that corrosion is a very important factor for low cycle life. Therefore, the effect of alloying on a probable corrosion mechanism, which is the disintegration of CaNi₅ due to Ca hydroxide formation via Ca diffusion, is also investigated by first principle methods.

In literature there are limited studies for CaNi₅. Therefore, it is difficult to discuss and comment on results of proper alloying of CaNi₅. In this manner, same study has been carried on for LaNi₅ because low cycle life problem of LaNi₅ were solved by proper alloying and today LaNi₅ is the commercial active material for Ni-MH batteries. Therefore, as done for CaNi₅ effects of alloying was studied using an ab initio pseudo potential method. Formation energies of the LaNi₅ compounds having different alloying elements were calculated for the understanding of the effect of the alloying element on the stability of the compound. Also, NEB study was also carried on for LaNi₅.

As known, properties of materials are strongly related with the interactions of electrons and nuclei. Therefore, Schrodinger Equation (S. E.) has opened a new gateway for materials science. However, analytical and numerical solutions of S. E. were invaluable for chemistry and materials science until 1964 [8]. In the mid-1960s two fundamental mathematical theorems proved by Kohn and Hohenberg and the derivation of a set of equation by Kohn and Sham have formed the basis of Density Functional Theory (DFT) [9]. DFT is mainly based on the cast of the intractable complexity of the electron-electron interactions in many electron systems into an effective one-electron potential, which is a functional of the electron density only[10].

There are a number of methods for computer simulation techniques for materials science and chemistry. DFT has some advantages over other techniques such as less demanding computational effort, less computer time and better agreement with the experimental studies[11].

Today, DFT calculations have become a main stay of materials science and play an important role in many material research efforts. There are some reasons for this success. First of all, DFT can convert the many-body electronic problem to a self-consistent-field single particle calculations. In addition, despite the severe approximations such as exchange and correlation energy functional, DFT calculations have sufficient accuracy. Combination of high accuracy of

DFT calculations with the currently available computational power and modern numerical algorithms makes DFT calculations feasible for realistic models of systems[12].

LITERATURE REVIEW

First principle studies are playing a very important role in many field of material science because they guide experimental works and save time. First principle studies are used to understand and optimize electrode materials in the battery industry since many of the relevant properties of battery such as voltage, capacity, structural stability, etc. are directly related with the electrode material [13].

In this manner, there are a number of studies for electrode materials of Li – ion batteries, Ni – MH batteries. Especially, studies for Li – ion batteries are very common. For example, Reed and Van Der Ven have investigated activation barriers of two stages of the transformation from layered Li_xMnO₂ to defective spinel-like form upon cycling by first principle studies [14]. In a different study, Aydinol et al. have used first principle's method to predict the intercalation voltage for lithium in metal oxides. In this study, average intercalation voltage of LiMO₂ cathodes was computed for different elements such as M = Ti, V, Co, Ni and Cu using pseudopotential technique[15]. In addition, Ouyang et al. have investigated the energy barriers for possible spatial hopping pathways for diffusion of Li ions in the olivine LiFePO₄ by adiabatic trajectory method which is based on density functional based total energy calculations [16]. It is possible to increase different examples of first principle studies for Li – ion batteries.

First principle methods are used not only for prediction of properties of Li – ion battery electrodes, but also they are used for optimize properties of intermetallics which are used as hydrogen storage materials and electrode materials of Ni – MH batteries. For example, Kecik and Aydinol has investigated the adsorption characteristic of hydrogen on magnesium surface. In this manner, Mg surface was alloyed with selected elements in order to calculate substitutional and on-surface adsorption energies. In addition, charge density differences of substitutionally doped surface configurations were investigated [17]. In their study, Pauw et al. tried to find solutions for high stability of MgH₂ and extremely slow desorption rate of MgH₂ by density functional theory. For this purpose, stability of two different crystallographic modifications of Mg-transition metal (Sc, Ti, Zr, Hf) dihydrides was investigated [18]. In an another study, dissociative adsorption of H₂ on FeTi surface was investigated via ab initio pseudopotential-plane wave method by Izanlou and Aydinol. For this purpose, adsorption energies of H atom and H₂ molecule on Fe and Ti terminated surfaces were calculated. Also, activation energies for possible dissociation paths of H₂ molecule were investigated by climbing image nudged elastic band method [19]. NEB studies are also very common in literature. For example, Tezuka et al.

have investigated hydrogen hopping paths in LaNi₅H solid solution by first principle calculations. In this study, activation energy for diffusion of hydrogen atoms in the structure were calculated by NEB method [20].

As mentioned below, today, LaNi₅ is used as anode material in Ni – MH battery. Therefore, first principle studies about LaNi5 were investigated. In one of the first first principles study about LaNi₅, Malik et al. have calculated the spin-polarized energy bands, the density of states, and the magnetic moments using the self-consistent augmented-plane-wave method [21]. Later, In 1998, Nakamura et al. have investigated the electronic structure and energetics of LaNi₅, its hydrogen solution (La₂Ni₁₀H) and its hydride (LaNi₅H₇) by the tight-binding linear muffin-tin orbital method [22]. In a different study, first principles electronic structure calculations have been used to investigate vacancy formation in LaNi5. It was found on this study that, Ni vacancies are mainly formed at the 2c sites in the hydrogen absorption-desorption cycle in LaNi₅ [23]. In their study, Yu et al. have calculated phonon dispersion curves and the phonon density of states in order to investigate thermodynamic and dynamical properties of LaNi5. In this study, it was found that, lattice parameters didn't differ more than 0.6 % from experimental data. Also, using the calculated phonon density of states, thermodynamic functions of LaNi5 were determined with the harmonic approximation [24]. In an another study, Zhang et al. have investigated the structure and elasticity of LaNi₅ and LaNi_{4.25}Al_{0.75}. They have indicated that, Al atoms prefer to substitute Ni atoms in the 3g site [25]. Moreover, Herbst and Hector have discussed the systematic theoretical results for La(TM)₅H_a materials (TM = Fe, Co and Ni) where enthalpies of formation and saturation hydrogen contents derived from density functional theory and Miedema's model were compared [26]. As can be seen, there are many different first principles studies about LaNi₅. These studies generally give background information for experimental studies.

As mentioned above, $LaNi_5$ the most widely used commercial active materials for Ni – MH battery. However, there were some problems with the $LaNi_5$ such as low cycle life and relatively high cost of $LaNi_5$. Low cycle life is strongly related with the instability and corrosion sensitivity of $LaNi_5$ [27]. Therefore, storage capacity of $LaNi_5$ decreases during charging and discharging cycles dramatically because $LaNi_5$ decomposes to $La(OH)_3$, Ni(OH)₂ and Ni as can be seen on following reaction.

$$LaNi_5 + 13 OH^- \longleftarrow La(OH)_3 + 5 Ni(OH)_2 + 13 e^-$$
(3)

Decomposition to $La(OH)_3$ and Ni was proved in many studies. For example, Boonstra et al. have found that, capacity decay of $LaNi_5$ electrode is related with the degradation process of $LaNi_5$ with the formation of $La(OH)_3$ and $Ni(OH)_2$ by x-ray diffraction measurements. Also it was stated that, equation 3 is the dominant degradation mechanism of $LaNi_5$ during charge discharge cycle [28]. In addition, Han and Lee have investigated the hydrogen absorption and desorption behavior of LaNi₅. In their study, Ni clusters were found on the surface of alloys by magnetization measurements [29]. Moreover, formation of La(OH)₃ needles on surface of LaNi₅ after about 12 electrochemical cycles was determined by TEM [30].

Investigation of corrosion mechanism of LaNi₅ is very important in order to understand capacity decay and low cycle life. For this purpose, Willems and Buschow have investigated the degradation mechanism in their study. According to their study, corrosion reaction entails the diffusion of La from bulk to surface. Normally, La in the crystal structure of LaNi₅ is immobile at room temperature. However, as can be seen in equation (2), there is a hydrogen storage while charging and because of this hydrogen storage, hydrogen-rich and hydrogen-poor regions occurs in the structure. Difference in volume between these regions severely distort lattice which distortion enhances mobility of La atom in the structure. Therefore, near the surface, a zone with a lower La concentration than the average concentration occurs. Lattice defects introduced during charging creates short-circuit diffusion paths for La atoms. Therefore La atoms move gradually and step by step into La depleted zone. From the La depleted zone, La atoms continue to diffuse to surface in order to form $La(OH)_3$ by reacting with the alkaline solution. Formation of thick La(OH)₃ layer on surface and decrease in La content in the structure inhibit hydrogen absorption [30]. Pulverization of LaNi5 is an another problem for capacity decay because oxidized surface area increases. Probable reason of pulverization is the internal stresses due to the volume expansion during hydrogen absorption since volume expansion of LaNi₅ on hydriding is about 24 % [30]. In this manner, Sakai et al. have examined the mechanical properties of alloys. It was determined that the lower the Vickers hardness leads to the slower the pulverizing rate which increase cycle life of alloys [31, 32].

In this regard, scientist tried to solve capacity decay problem of LaNi₅ by proper alloying. Generally, studies focused to Ni site substitution. For example, Willems and Buschow have investigated charge and discharge behaviors of LaNi_{5-x}Co_x, LaNi₄Cu and LaNi_{5-x}Co_xAl_{0.1}. According to results of this study, Cu substitution has no considerable effect on cycle life of LaNi₅. On the other hand, it was observed that, Co substitution improves cycle life of LaNi₅. In fact, increase in x values up to 3.3 in LaNi_{5-x}Co_x gives better results. Also, Al addition to Co substitution gives very good results. Therefore, LaNi_{1.9}Co₃Al_{0.1} gives the best overall performance [30]. These positive results of Co substitution of Co for Ni in LaNi₅ results in a considerable reduction of the volume expansion on hydrogen absorption [33]. Finally, Willems and Buschow have studied the behavior of compounds in which La was partially substituted such as La_{0.8}Nd_{0.2}Ni_{2.5}Co_{2.4}S_{0.1}. With this compound, excellent stability obtained and after one thousand cycles capacity have decreased only 30% [30]. In an another study, Sakai et al. have

investigated the properties of LaNi_{5-x}M_x(M=Ni, Mn, Cu, Cr, Al and Co). In their study, capacity decay ratios after 150 cycles at a cut-off voltage of -0.5 V were calculated for alloys LaNi_{4.5}M_{0.5}, LaNi₄M (M=Mn, Cu, Cr, Al) and LaNi_{2.5}Co_{2.5}. It was found that, increase in M content decreases capacity but increases cycle life. In addition, AI and Co are very effective in order to increase cycle life of LaNi₅. On the other hand, Mn adversely affect cycle life of LaNi₅ [31]. Similarly, Chartouni et al. have investigated mechanical and electrochemical properties of LaNi₅, LaNi₄Co, $LaNi_{4.5}AI_{0.5}$, $Zr_{0.2}La_{0.8}Ni_{4.5}AI_{0.5}$, $Er_{0.2}La_{0.8}Ni_{4.5}AI_{0.5}$ and $LaNi_{3.5}CoAI_{0.5}$ alloys. According to their results, after 150 cycles, LaNi_{3.5}CoAl_{0.5} has lost its capacity only 90 %. Also partial substitution of La with Er and Zr gave very good cycle life in this study. In addition, direct relationship between hardness of the alloy and cycle life has been shown. It was found that, decrease in Vickers hardness leads to increase in cycle stability. For example, LaNi5 with the lowest cycle stability has 809 kg.mm⁻² Vickers hardness, on the other hand, $LaNi_{3.5}CoAI_{0.5}$ with the best cycle stability has 762 kg.mm⁻² Vickers hardness. Moreover, it was determined that, LaNi_{3.5}CoAl_{0.5} shows the slowest decrease in surface La content which is the reason for highest cyclic stability [32]. In an another study, Sakai et al. have partially substituted La with Ce, Nd and Zr, Ni with Co and Al. It was observed that, these elements are effective in order to improve cycle life of LaNi5. In this study, alloy of La_{0.8}Nd_{0.15}Zr_{0.05}Ni_{3.8}Co_{0.7}Al_{0.5} has best overall performance [34]. Also, Mg was substituted with La atom by Cuscueta et al. and positive effect of Mg substitution on cycle life was determined. it was found that La_{0.85}Mg_{0.15}Ni_{3.8}Co_{0.3}Mn_{0.3}Al_{0.4} alloy has performed the best results on cyclic stability, with a capacity reduction of 4.4% at cycle 50 and a reduction rate of 0.117mAh/g per cycle [35]. As can be seen similar elements were studied by different scientists. In a comparative study, LaNi_{4.7}M_{0.3} (M = Ni, Co, Mn and Al) alloys were investigated by Liu et al. As found on previous studies, Mn decreases cycle life of LaNi5, on the other hand, Co and Al increases cycle life of LaNi5 and it was stated that Co is more effective that the AI in order to improve cycle life of LaNi₅ [36]. Positive effects of Co and Al were discussed by Reilly et al. Formation of stable Co and Al oxide layer on the surface of alloys restrict further corrosion of alloy. Since Co oxide layer is conductive and more stable than the Al oxide layer, Co is more effective in order to improve cycle life of LaNi₅ [27]. For Ni site substitution different elements were tried also. For example, Meli et al. have studied iron-containing LaNi5 alloys. It was found on this study that partial substitution of Ni with Fe has no effect on cyclic durability of LaNi5. According to capacity measurements, after 200 cycle, capacity of LaNi_{4.5}Fe_{0.5} decreases about 60 %. On the other hand, it was observed that, combined substitution of Fe and Al increases cyclic durability of LaNi5. After electrochemical cycling, on the surface of alloys, no Fe enrichment was observed but a small amount Al enrichment observed by XPS [37]. In addition, Züttel et al. have observed that, partial replacement of La with Al, Mn, Co and Fe gives better cyclic durability than the non-iron containing alloys because of the smaller volume expansion [38]. Deng et al. have studied the electrochemical performance of LaNi₅Sn_x alloys. It was stated on this study that Sn improves cycle life of LaNi₅, but there is no a linear relationship between

amount of Sn and electrochemical performance. It was found that LaNi_{4.58}Sn_{0.42} gives the best overall performance [39]. Witham et al. have compared LaNi_{5-x}Si_x and LaNi_{5-x}Ge_x alloys in their studies. They have found that, Ge is more effective than the Si in order to improve cycle life of LaNi₅ and the optimum Ge content for LaNi_{5-x}Ge_x alloys is in the range 0.4 < x < 0.5 [40]. Effect of Ti and Zr additions were also investigated by Seo et al. and it was stated that only small amount Ti and Zr addition are effective in order to improve cycle life of the alloy $(LMNi_{3.6}Al_{0.4}Co_{0.7}Mn_{0.3})M_v$ (LM = La – rich mischmetal, M = Ti and Zr). It was found that, addition of Ti with y = 0.05 and Zr with y = 0.02 improve cycle life of the alloy. On the other hand, addition of higher amounts Ti and Zr adversely affect cycle life of the alloy [41]. There are also studies for La site substitution. For example, effect of partial substitution of La with Ce, Pr and Nd were investigated by Chen [42]. It was observed that, $La_{0.7}Ce_{0.3}B_5$ (B = Ni_{3.55}Co_{0.75}Mn_{0.4}Al_{0.3}) gives the best cycle life. Effect of Ce on cycle life of alloys was explained by formation of protective CeO₂ oxide layer [42]. In addition, Moussa et al. have compared the electrochemical properties of MmNi_{3.55}Mn_{0.4}Al_{0.3}Co_{0.75} and LaNi_{3.55}Mn_{0.4}Al_{0.3}Co_{0.75} alloys and it was found that, capacity decay in Mm containing alloy is slower than the LaNi_{3.55}Mn_{0.4}Al_{0.3}Co_{0.75}. Also Mm containing alloy has better electrochemical properties [43].

As can be seen on studies, low cycle life due to the rapid capacity decay problem of LaNi₅ was solved by proper alloying. Today, different LaNi₅ alloys are used in Ni – MH batteries. For example, Moussa et al. have showed that, compared to the LaNi₅ compound, MmNi_{3.55}Mn_{0.4}Al_{0.3}Co_{0.6}Fe_{0.15} has a better stability in the alkaline solution, a good reversibility and a good kinetic of the electrochemical reaction [44]. However as mentioned above, La is a relatively expensive rare earth element. Therefore, other alternatives for LaNi₅ are searched. CaNi₅, belonging to same crystal structure with LaNi₅, turns out to be an important alternative. CaNi₅ has higher specific hydrogen storage capacity than LaNi₅. Also, theoretical capacity of CaNi₅ is 482mAhg⁻¹, while it is 372 mAhg⁻¹ for LaNi₅ [7]. In this regard, CaNi₅ has a very important potential to be an alternative for LaNi₅, during charge and discharge cycle, capacity decays because of the electrochemical corrosion of Ca as can be seen in equation (4) [45]. Calcium segregation from bulk to surface was also detected in studies [46, 47]. Therefore, scientists tried to improve cycle life of CaNi₅ by proper alloying as in LaNi₅.

CaNi₅ + 2 H₂0 \leftarrow Ca(OH)₂ + 2 H⁺ + 5 Ni + 2 e⁻ (4)

In literature, the number of studies related to the effect of alloying on the cycle life of $CaNi_5$ is quite low. Li and Suda have studied Ca and Ni site substitutions. Generally, they have stated that, instead of Ni site substitution, Ca site substitution would be more effective in order to increase cycle life of $CaNi_5$ [45]. According to their results, Al substitution with Ni cannot improve cycle life of alloy. On the other hand, combined substitution of Ca with La and Ni with Al have

improved cycle life of CaNi₅, where substitution also restricts the formation of Ca₂Ni₇ and Ni-rich phases. In fact, increase in amount of La content gives better results until the x = 0.7 in the alloy of Ca_{1-x}La_xNi_{4.7}Al_{0.3}. This positive effect of La substitution might be caused by the increase of the pulverization easiness of the alloy. Co substitution with Ni site was combined with La substitution and it was found that there is no any effect of Co substitution on cycle durability of $Ca_{0.5}La_{0.5}Ni_{5-1}$ _xCo_x alloy. In addition, it was found in this study that, instead of La substitution with Ca, Ce substitution gives better results in the same alloy for x = 0.2 amount since it can not only decrease pulverization easiness of the alloy but also improve the lattice stability. Moreover, it was stated that, Mg substitution have also positive effect on cycle durability of CaNi5 with the formation of more stable protective surface layer of $Mg(OH)_2$ [7]. In an another study of Li and Suda, effects of Ti and Zr additions on cycle durability of Ca_{0.4}La_{0.6}Ni_{4.7}Al_{0.3} alloy were investigated. It was found that, Ti and Zr improves cycle durability of alloy with the formation of protective oxide layer on the surface of alloy [48] and Ca_{0.4}La_{0.6}Zr_{0.15}Ni_{4.7}Al_{0.3} alloy gives the best overall cyclic durability performance [45]. On the other hand, Jensen and Bjerrum, alloyed CaNi₅ by adding 10 at. % Al, Cr, Mn, Fe, Co, Cu, Zn, Sn and Mg. They found that, there was no improvement in the cycle life. It was also stated that, crystal structure of CaNi5 cannot be preserved [49]. Moreover for hydrogen storage, Liang et al. (2001) found that, Sn substitution for Ni by mechanical alloying resulted in new phase formation after heat treatment and this new phase cannot absorb hydrogen [50].

As listed above, there are many studies in order to improve cycle life and decrease cost of LaNi₅ and CaNi₅. Generally, cycle life was improved by several mechanism such as formation of protective surface layer on surface of alloy, reduction of volume expansion on hydrogen absorption and decrease pulverization rate of alloy. However, according to Willems and Buschow, oxide layer on the surface inhibits hydrogen absorption and desorption. In addition, protective effect of surface layer can only be present when volume expansion is not too much. Therefore, protective effect of surface layer decreases; because, LaNi₅ expands about 24 % while hydrogen storage [30].

In this manner, in this study, in order to investigate the stability of different La-Ni and Ca-Ni based alloys, 48 different alloying elements were selected from the periodic table and the formation energy of the La-Ni and Ca-Ni based alloys were calculated using ab initio pseudo potential method because phase stability would be one of the important factors on cycle life like formation of stable oxide layer on surface of alloy. In addition, as mentioned above, La atoms diffuse from bulk to surface due to several distortions in the crystal structure of the LaNi₅ in order to form La(OH)₃ by reacting with the alkaline solution [30]. Same corrosion mechanism can be possible in CaNi₅ because of the same crystal structure, same hydrogen absorption desorption mechanism and charge discharge mechanism. Therefore, in order to understand effects of

10

alloying on diffusion barriers, diffusion of La atom in the crystal structure of LaNi₅ and Ca atom in the crystal structure of CaNi₅ was investigated by NEB method. Moreover, in order to understand the hydride stability in alloyed CaNi₅, formation energies of Ca₇Ni₄₀MH₄₈ and Ca₈Ni₃₉MH₄₈ were calculated.

CHAPTER 2

COMPUTATIONAL METHODOLOGY

In this study, formation energies of La-Ni and Ca-Ni based alloys were calculated. In addition, in order to understand effects of alloying on diffusion barriers, diffusion of La atom in the crystal structure of LaNi₅ and Ca atom in the crystal structure of CaNi₅ was calculated by NEB method. All calculations were performed in a plane wave basis set using the projector augmented wave (PAW) method [51] within the formalism of density functional theory as implemented in the VASP program [52-54]. In the calculations, PAW potentials [55] were used, where exchange-correlation functional with the generalized gradient approximation (GGA) is in Perdew-Burke-Ernzerhow functional (PBE) form [56].

3.1 Bulk Calculations for CaNi₅ and LaNi₅

Bulk calculations in CaNi₅ structure were performed for several test purposes. CaNi₅ adopt the hexagonal CaCu₅ crystal structure, Fig. 1, in which there are five nickel atoms (2c and 3g Wyckoff positions) and one calcium atom (1a Wyckoff position) within the unit cell having the symmetry of the P6/mmm space group. After setting up the simulation cells in the bulk sense with periodic boundary conditions, the cell volume and the atomic positions are allowed to relax to find the minimum energy configuration. During these calculations, sampling in the reciprocal space (*k*-point grid size) and spin polarization effect were considered to attain a few meV convergence. It was found that, $16 \times 16 \times 16$ gamma centered grid of *k*-point sampling is adequate for CaNi₅. Expectedly, since Ni is a magnetic element, electronic structure and the density of states (DOS) of the compound changes with respect to spin polarization Fig 2. Therefore, spin polarization has been taken into account in all calculations hereafter. The calculated lattice parameters of the compound were found to be in agreement with the experimental values with less than 0.5% error.

Figure 2. Electronic density of states of $CaNi_5$, showing spin up and spin down states. For the alloying calculations a super-cell, composed of 2×2×2 unit cells was constructed, Fig. 3. for $CaNi_5$. Therefore there are a total of 8 calcium and 40 nickel atoms in this cell, in which either

one calcium or one nickel atom will then be substituted by the alloying element later in the calculations. There are, however, two non-equivalent Ni sites in the structure. One is at the same crystal plane as that of Ca (called as Ni-1 site) and the other one lies above this plane (called Ni-2 site). In order to understand which Ni site is preferred by the alloying element, we therefore considered both. Once the alloyed super cell is formed, cell volume and atomic positions are all allowed to relax again to find the minimum energy configuration. In all alloying calculations, spin polarization was taken into account and a gamma centered grid of $3 \times 3 \times 4 k$ -point set was used corresponding to 9 *k*-points in the irreducible Brillouin zone. In the expansion of the plane-wave basis set, a kinetic energy cut off of 400 eV was used. The overall convergence in the total energy is less than about 10 meV per unit cell.

Since LaNi₅ has the same CaCu₅ crystal structure, a similar 2x2x2 unit cell constructed for LaNi₅ calculations. In addition, same *k*-point sampling and kinetic energy cutoff values were used.

Figure 3. The super-cell used in alloying calculations. Ca, Ni-1 and Ni-2 sites are shown.

In case of La-site substitution, the structure has a unit formula of $La_7Ni_{40}M$, M being one of the 48 alloying elements. For Ni-site substitution we have $La_8Ni_{39}M$. The composition of the alloy in terms of the alloying element is, therefore 2.08 at.%. The corresponding alloying reactions are,

(6)

for La and Ni-site substitution respectively. Formation energy of the alloy then can be calculated by taking the difference of the calculated total energies of the product and the reactants of the above alloying reactions. More specifically, for La and Ni-site substitution they are given as below.

(7)

(8)

Similarly, for Ca-site substitution, the structure has a unit formula of $Ca_7Ni_{40}M$, M being one of the 48 alloying elements. For Ni-site substitution we have $Ca_8Ni_{39}M$. The composition of the alloy in terms of the alloying element is, therefore 2.08 at.%. The corresponding alloying reactions are,

(9)

(10)

for Ca and Ni-site substitution respectively. Formation energy of the alloy then can be calculated by taking the difference of the calculated total energies of the product and the reactants of the above alloying reactions. More specifically, for Ca and Ni-site substitution they are given as below.

As known from electrochemical reactions of a Ni – MH battery, hydrogen atoms are stored on anode materials. Current density, capacity and other properties of battery is directly related with the release of these hydrogen atoms from anode. In this manner, effect of alloying on formation energy of hydride compounds of CaNi₅ were calculated and compared with the pure hydride compound.

Unfortunately, there are very limited study about hydride compounds of CaNi₅. Therefore, literature of LaNi₅ was surveyed and it was found that LaNi₅ can store six hydrogen atoms per formula. When crystal structure of these hydride compounds were investigated, it was understood that hydrogen atoms does not fill Wyckoff positions exactly [57]. Therefore, there are different crystal structures which have different space groups because of the different positions

of hydrogen atoms. However, when hydrogen atoms are deleted, crystal structure is CaCu₅ crystal structure. Therefore, one of the crystal structure of hydride compounds of LaNi₅ was selected for CaNi₅ calculations because CaNi₅ also belongs to CaCu₅ crystal structure. Selected crystal structure for calculation of formation energy of hydride compounds of CaNi₅ belongs to space group of 157, Ca atom are positioned at 1a, Ni atoms are positioned at 2b and 3c and H atoms are positioned at 3c and 6d Wyckoff positions. However, only half of the 6d Wyckoff position is filled by hydrogen atoms Fig. 4. Therefore, in order to calculate formation energies of hydride compounds of CaNi₅, exact position of hydrogen atoms should be determined. In this manner, for six position, total energies of ten possible combination structures were calculated and positions were named by their position number Fig. 4. Total energies of ten possible combination is given on following table.

Figure 4. Six possible position for three hydrogen atoms named by numbers.

Table 3. Total energies of ten possible combinatio

Combination of Positions	Total Energy (eV)
(123)	-51.988
(134)	-51.925
(136)	-51.924
(126)	-51.928
(156)	-51.919
(253)	-51.930
(256)	-51.930
(362)	-51.972
(356)	-51.973
(456)	-51.993

As can be seen on Table 3. the most stable combinations are (123) (and its crystallographic equivalent (456)) and (356) (and its crystallographic equivalent (362)) because of the lower energy state. In this manner, by using these hydrogen atom positions, total energies and formation energies of $Ca_7Ni_{40}MH_{48}$ and $Ca_8Ni_{39}MH_{48}$ compounds were calculated according to corresponding reactions for Ca and Ni-site substitution respectively,

(13)

(14)

Formation energy of the hydrides then can be calculated by taking the difference of the calculated total energies of the product and the reactants of the above hydriding reactions. More specifically, for Ca and Ni-site substitution they are given as below.

(15)

3.2 NEB calculations for CaNi₅ and LaNi₅

The NEB method is used to find the minimum energy path (MEP) between a given initial and final state of reaction [58, 59] and the MEP can be used to estimate the activation energy barrier for transition between the initial and final states. Any maximum along the MEP is a saddle point on the potential surface and energy of the highest saddle point gives the activation energy of the reaction [59]. In this study, the climbing image NEB (CI-NEB) method which is a modified version of NEB is used [58]. By this method, with a rigorous convergence to a saddle point, exact position of saddle point can be obtained.

For CI-NEB calculations, diffusion path of Ca atom determined and as can be seen on Fig. 5 Ca atoms diffuse through Ni tubes. For initial state Fig. 6, one Ca atom was taken out from 2x2x2 super cell and system was relaxed without cell shape relaxation. Similarly for final state, next Ca atom on Ni tube was taken out and system was relaxed without cell shape relaxation Fig. 7. For calculations as a kinetic energy cutoff of 400 eV and gamma centered grid of 2×2×3 *k*-point set were used.

Figure 5. Ca atoms diffuse through these Ni tubes.

Figure 6. Initial state for NEB calculations.

Figure 7. Final state for NEB calculations.

Due to the same crystal structure, same procedure was used for CI-NEB calculations of LaNi₅. Also same *k*-point sampling and kinetic energy cutoff values were used for CI-NEB calculations of LaNi₅.

CHAPTER 3

RESULTS AND DISCUSSION

4.1 Calculations for CaNi5

4.1.1 Calculation of Formation Energy

As mentioned above, firstly bulk calculations were performed. As can be seen on equation 7, 8 10 and 11 for calculation of formation energies, total energies of pure structures are needed. Therefore, pure $LaNi_5$, $CaNi_5$ and alloying elements were relaxed and total energies were calculated Table 4.

From Table 4, it can be concluded that, the difference between calculated lattice parameters and experimental results does not change more than % 3 except for a few elements. Also, for CaNi₅ and LaNi₅, difference is lower than %0.5. These differences between calculated and experimental lattice parameters are very successful for a first principle study. In addition, as can be seen on Table 4. LaNi₅ is more stable than CaNi₅ because of the lower energy state. Therefore, it would be more difficult to make CaNi₅ more stable than LaNi₅.

Then, as mentioned above, different alloying elements were replaced with one calcium atom, with one nickel atom in plane with calcium atom (Ni – 1 site) and with one nickel atom out of plane with calcium atom (Ni – 2 site). Therefore, $Ca_7Ni_{40}M$ and $Ca_8Ni_{39}M$ alloys were obtained and relaxed. Formation energies of $Ca_7Ni_{40}M$ and $Ca_8Ni_{39}M$ alloys were calculated by equations 11 and 12. Lattice parameters, total energies and formation energies of $Ca_7Ni_{40}M$ and $Ca_8Ni_{39}M$ alloys were tabulated on Tables 5, 6, and 7.

Table 7.Lattice parameters, total energies and formation energies of Ni-2 site substitution alloys.

In order to see effect of alloying on stability of CaNi₅, formation energies of alloys were compared with the formation energy of the pure CaNi₅, Table 8 and Fig 8. As can be seen from Table 8, early transition metals of group 3 and 4, lanthanides and actinides are all effective in lowering the formation energy of CaNi₅ and they preferentially replace the calcium atom in the structure. Sc, Ti, Zr and Hf can also substitute Ni in both Ni-1 and Ni-2 sites. In addition, Al, Si, Ge and P were found to be very effective and they can replace Ni in both Ni sites. Less effective than these, Ni can also be substituted by Zn, Sn and Sb. All of the above elements lower the formation energy of CaNi₅, therefore a more stable alloy is formed which may increase the cyclic durability.

Figure 8. On the periodic table % change in the formation energy of CaNi₅ with alloying.

If these results are compared with the results found in literature, some agreement can be seen. For example, according to Li and Suda [7], La and Ce addition improves cycle life, while they are also found to lower the formation energy. A similar agreement can also be seen in Al, Zr and Ti added alloys. However, in literature it was stated that, Ce, Zr and Ti improves cycle life with increasing lattice stability or formation of stable oxide layer on surface [7, 45, 48]. This means that, there would be different mechanisms to improve cycle life of CaNi₅ and it is hard to discuss which one more effective. On the other hand, according to Willems and Bushow's study [30], protective effect of the surface layer will be present only when the volume expansion while hydrogen absorbing is not too much. Therefore, increasing thermodynamical stability of the alloy would be also effective and important to increase cycle stability of CaNi₅. In addition, it was reported in literature that, Fe and Co elements do not have any effect on the cycle life of CaNi₅ [7, 49]. As can be seen in Table 8, these elements cause an increase in the formation energy of the system, which means that the compound becomes less stable.

In addition, it is known from literature that [30], lattice distortions enhance mobility of Ca atom and which leads to corrosion of CaNi₅. Therefore, effect of alloying on lattice parameters were investigated. According to Table 5, 6 and 7, it is seen that, for Ca site substitution, especially rare earth elements has little effect on lattice parameters. Ac has maximum effect relative to other rare earth elements on lattice parameters with 0.34 % increase in a and 0.14 % decrease in c. On the other hand, early transition metals such as Hf, Zr, Sc and Y distort lattice about between 0.17 % and 0.7 %. For Ni site substitution, except Al, Cu, Ti and Zn, all elements which decrease formation energy of alloy distort lattice much more relative to Ca site substitution. For example rare earth elements distort lattice parameters more than 1 % and also some transition metals effect about 0.8 %.

As mentioned above, activation energies of diffusion of Ca atom in crystal structure were calculated for different alloying elements and different substitution sites by NEB method. To select alloying elements for NEB calculations, firstly effects of alloying elements of formation energy (Table 8) were investigated and alloying elements which decrease formation energy of CaNi₅ were selected. Secondly, as mentioned before, there are nickel tubes in CaCu₅ structure and alloying elements which makes nickel tubes narrow were selected. For this purpose, distance between two opposite nickel atom on nickel tube was found and compared with the pure CaNi₅, Table 8. In all substitutions, three distances were identified for six nickel atoms and it was found that two distances are same with each other and only one is different. Therefore, there are same distances and different distance titles on Table 9. In this manner, alloying elements for NEB calculations were selected according to Table 8 and 9 and tabulated on Table 10, Table 11 and Table 12. For Ca site substitution, Al, Fe, P, Si, Sn, V and Zn were selected for

NEB calculations. Activation energies can be seen on graphs of diffusion of Ca atom in Figure 9, 10 and 11. It was found that, activation energy of Ca atom on pure $CaNi_5$ structure is 0,89191 eV.

Table 10. Activation energies and change in the activation energy for Ca site substitution

It can be concluded from Table 10 that, Ti has little effect on formation energy of CaNi₅, but it increases activation energy for diffusion of Ca atom about %22. Therefore, for Ca site substitution, addition to formation of sable oxide layer on surface, Ti can improve cycle life by increasing activation energy for diffusion of Ca atom in the structure. Interestingly, Hf and Zr not only decrease formation energy of system but they also increase activation energy for diffusion of Ca atom in the structure more diffusion of Ca atom considerably which makes diffusion of Ca atom in the structure more difficult. Therefore, it can be concluded that, these elements would be effective to improve cycle life of CaNi₅. Also rare earths which decrease formation energy of system has little effect on activation energy for diffusion of Ca atom.

Zn	0.950	6.536	-10.24	0.8919

Table 12 Activation energies and change in the activation energy for Ni-2 site substitution.

Element	Activation Energy (eV)	% Change in Activation Energy	% Change in Formation Energy	Activation Energy of Pure CaNi₅ (eV)
AI	0.753	-15.513	-22.35	0.8919
Fe	0.814	-8.699	3.25	0.8919
P	0.770	-13.559	-33.08	0.8919
Si	0.813	-8.752	-30.24	0.8919
Sn	0.748	-16.103	-10.76	0.8919
V	0.709	-20.424	0.73	0.8919
Zn	0.797	-10.566	-8.76	0.8919

As can be seen in Table 11 and Table 12, for Ni-1 site substitution, except P, all elements which decrease formation energy of system also increase the activation energy of diffusion of Ca atom. However, if we look for change in energy on formation energy of system, all these elements, except Zn, prefer Ni-2 site substitution because of lower energy state. As can be seen on Table 12, if these elements substitute with Ni-2 site all elements decrease activation energy of diffusion of Ca atom, which makes diffusion of Ca atom easier.

Figure 10. Activation energies of diffusion of Ca atom in the structure for Ni-1 site substitution

4.1.2 Formation Energy Calculations for Hydride Compounds of CaNi₅

As known from electrochemical reactions of a Ni – MH battery, hydrogen atoms are stored on anode materials. Current density, capacity and other properties of battery is directly related with the release of these hydrogen atoms from anode. In this manner, effect of alloying on formation energy of hydride compounds of CaNi₅ were calculated and compared with the pure hydride compound. When hydrogen atoms were positioned at (123) Fig. 3, formation energy of pure CaNi₅H₆ was calculated as -1.233 eV and when hydrogen atoms were positioned at (356) Fig. 3, formation energy of pure Ca₈Ni₄₀H₄₈ was calculated as -1.27 eV. In addition, calculations were done for Ca₇Ni₄₀MH₄₈ and Ca₈Ni₃₉MH₄₈ compounds and effect of alloying on formation energy of these alloys were investigated and compared with the pure Ca₈Ni₄₀H₄₈, Table 13.

 Table 13. % Change in the formation energy of hydride compounds of CaNi₅ for alloying elements.

As mentioned above, capacity of battery is directly related with the release of the hydrogen stored. If hydride is too stable, capacity of active material may decrease because hydrogen cannot be released easily. Therefore, if proper alloying decrease formation energy of $Ca_{(1-x)}Ni_5M_x$

and $CaNi_{(5-x)}M_x$ compounds, cycle life would probably increase. However, if proper alloying decrease the formation energy of hydride compounds, reversible capacity of active material would probably decrease. In addition, contrary to decrease in formation energy of hydride compounds, if formation energy of hydride compounds increase, active material cannot be charged completely.

In this respect, when Table 8 and 13 investigated, it can be seen that, substitution of Ca with La, Ce and Yb do not change the formation energy of $CaNi_5H_6$ too much. Other rare earth elements and Y decrease formation energy of $CaNi_5H_6$ by 5 to 7 % when substituted with the Ca. Zr and Hf, however, decrease the formation energy of the hydride by more than 10% if replace with Ca atom. On the other hand, all early transition metals including Zr and Hf decrease the hydride stability if they substitute Ni sites. Other elements replacing Ni sites (AI, Si, Ge, P Sn and Zn) which decrease formation energy of CaNi₅, decrease the formation energy of the hydride too.

In addition, as mentioned above, lattice expansions because of the hydrogen absorption, enhance mobility of Ca atom [30]. According to lattice parameter calculations, volume of pure CaNi₅ increases about 22.53 % for (123) positions and 23.76 % for (356) positions while hydrogen absorbing. Therefore, in order to investigate effect of alloying on lattice parameters of CaNi₅ hydride compounds, lattice parameters of hydride compounds were calculated (Tables 14, 15 and 16). Also change in the volume while hydrogen absorbing were calculated and compared with that for pure CaNi₅ as seen in Table 17.

Table 17. % change in volume expansion while hydrogen absorbing for different alloyingelements compared to pure CaNi₅ and its hydride.

According to Table 17, generally, change in the volume expansion for (356) position of hydrogen atoms is higher than that for (123) position of hydrogen atoms. For Ca site substitution, when

hydrogen atoms are positioned at (356) position, there is a little increase in volume expansions for rare earths and some early transition metals which decrease formation energy of CaNi₅. On the other hand, when hydrogen atoms are positioned at (123) positions volume expansion decreases. However, according to Table 13. when Ca atom is replaced with these elements, hydrogen atoms prefer (356) positions because of the lower energy state. For Ni site substitution, generally, Ni-2 site substitutions lower volume expansion while hydrogen absorbing. Especially, Hf, Mg, Sb, Sc, Sn, Zr and Ge decrease volume expansion while hydrogen absorbing much more according to pure CaNi₅ and also these elements decrease formation energy of CaNi₅. Therefore, it can be concluded for these elements one can expect less protective oxide film degradation.

4.2 Calculations for LaNi₅

4.2.1 Formation Energy Calculations

In literature there are limited studies for CaNi₅. Therefore, it is hard to discuss and comment on results of proper alloying of CaNi₅. In this manner, same study have been carried on for LaNi₅ because low cycle life problem of LaNi₅ was solved by proper alloying and today LaNi₅ is commercially active material for Ni-MH batteries. Also, as mentioned above, there are many studies for alloying of LaNi₅.

Same elements used for alloying of $CaNi_5$ were used for also alloying of $LaNi_5$. Alloying elements were replaced with one lanthanum atom, with one nickel atom in plane with lanthanum atom (Ni – 1 site) and with one nickel atom out of plane with lanthanum atom (Ni – 2 site). Therefore, $La_7Ni_{40}M$ and $La_8Ni_{39}M$ alloys were obtained and relaxed. Formation energies of $La_7Ni_{40}M$ and $La_8Ni_{39}M$ alloys were calculated by equations 7 and 8. Lattice parameters, total energies and formation energies of $La_7Ni_{40}M$ and $La_8Ni_{39}M$ alloys were tabulated on Table 17, 18, and 19.

In order to see effect of alloying on stability of LaNi₅, formation energies of alloys were compared with the formation energy of the pure LaNi₅, Table 20. As can be seen from Table 20, for La site substitution, some of the lanthanides, actinides and early transition metals of group 3 are effective for decreasing formation energy of LaNi₅. On the other hand, for Ni sites substitution, Al, Ge, P, Se, Se, Si, Ti and Zn are very effective to decrease formation energy of the system. In addition, less effectively, Ni can also be substituted with Au, Hf, Sb, Sc, Sn in order to lower formation energy of LaNi₅. As can be seen, it was determined that, all above elements lower

formation energy of $LaNi_5$, therefore a more stable alloy is formed which may increase the cyclic durability.

Table 21. Percent change in the formation energy of LaNi₅ due to alloying at La, Ni-1 and Ni-2 sites.

Some agreements can be seen between these results and results found in literature. For example, according to studies, AI, Ge, Si, Sn and Ti improves cycle life if they are replaced with Ni atom [30, 39-41] and it was found in this study that these elements decrease formation energy of system and they prefer Ni site substitution. However, in literature, it was stated that, these elements improve cycle life by formation of stable oxide layer on alloy surface and lowering the lattice expansion during hydriding. Therefore, it is hard to say which mechanism is dominant in order to improve cycle life of LaNi₅. A similar agreement can be seen in Fe added alloys. In literature, it was stated that Fe adversely effects the cycle life of LaNi₅ [37] and as can be seen on Table 21, Fe increases formation energy of system. In addition, in literature, it was found that, Ce, Pr, Co and Zr improves cycle life by formation of stable oxide layer on surface [30, 34, 42, 60]. On the other hand, in this study, it was found that they have no noticeable effect on formation energy of LaNi₅. Therefore, it can be said that instead of thermodynamic stability, formation of stable oxide layer on surface would be dominant mechanism for improvement of cycle life.

In addition, it is known from literature that [30], lattice distortions enhance mobility of La atom and which leads to corrosion of LaNi₅. Therefore, effect of alloying on lattice parameters were investigated. According to Table 18, 19 and 20, it is seen that, for La site substitution rare earth elements and some early transition metals has no considerable effect on lattice parameters. For Ni site substitution, except Sb, Si and Se, alloying elements which decrease formation energy of LaNi₅ has no considerable effect on lattice parameters.

4.2.2 NEB Calculations

As mentioned above, activation energies of diffusion of La atom in crystal structure were calculated for different alloying elements and different substitution sites by NEB method and tabulated on Table 22 - 24. Elements were selected for NEB calculations, according to their effect on formation energy of LaNi₅. Generally, elements which decrease formation energy of LaNi₅ were selected. In this manner, for La site substitution, Ca, Dy, Er, Gd, Sm, Y and Zr were selected and for Ni site substitution, AI, Co, Cu, P, Sb, Si and Ti were selected for NEB calculations. It was found that, activation energy for diffusion of La atom on pure LaNi₅ structure is 1,02 eV. In addition graphs of these activation energies are given on following Fig 12 - 14.

As mentioned before, formation energy of pure $CaNi_5$ was found as -30.547 eV and activation energy for diffusion of Ca atom in pure $CaNi_5$ structure was found as 0.89191 eV. On the other hand, formation energy of pure $LaNi_5$ was found as -34.53 eV and activation energy for diffusion of La atom on pure $LaNi_5$ structure was found as 1,02 eV. According to these results, $LaNi_5$ is more stable than $CaNi_5$ because of the lower energy state. Therefore, it may be more difficult to improve cycle life of $CaNi_5$ than the $LaNi_5$. In addition, as can be seen, energy barrier for diffusion of La atom in $LaNi_5$ is higher than the that for Ca in $CaNi_5$. This is the another reason for difficulty of improvement of cycle life of $CaNi_5$.

As can be seen on Table 22, alloying LaNi₅ with Ca leads not only to increase in formation energy but also decreases activation energy for diffusion of La atom. On the other hand, rare earth elements (Dy, Er, Gd and Sm) and Y decreases slightly formation energy of system and increases activation energy for diffusion of La atom. In this manner, it can be concluded that, these rare earth elements and Y would have positive effect on cyclic stability of LaNi₅. In addition, although Zr increases formation energy of system slightly , it has increased activation energy for diffusion of La atom sharply. In this manner, agreements can be seen with the results found in this study and literature. For example, positive effects of rare earth elements on cyclic durability of LaNi₅ were detected by Chen et al. [42] and in this study, it was found that rare earth elements substituted with La atom decrease formation energy of system and increase activation energy for diffusion of La atom in the structure. In addition, Chan et al. has determined the positive effect of Zr on cyclic durability of LaNi₅ [41]. In this study, it was found that, although Zr substitution has no any positive effect on formation energy, Zr substitution with La atom increases activation energy, Zr substitution with La atom

Element	Activation Energy (eV)	% Change in Activation Energy	% Change in Formation Energy	Activation Energy of Pure LaNi₅ (eV)

Sb	1.60833	57.61857	-0.559162	1.020
Si	1.27463	24.91535	-8.288358	1.020

Table 24. Activation energies and change in the activation energy for Ni-2 site substitution.

Element	Activation Energy (eV)	% Change in Activation Energy	% Change in Formation Energy	Activation Energy of Pure LaNi₅ (eV)
Al	0.774	-24.12556	-7.414073	1.020
Со	0.957	-6.14311	2.514626	1.020
Cu	0.964	-5.47582	0.845078	1.020
Р	0.835	-18.15885	-12.014775	1.020
Sb	0.655	-35.73371	-4.594572	1.020
Si	0.852	-16.45912	-10.866261	1.020
Ti	0.503	-50.67302	-1.496663	1.020

As can be seen on Table 23 and 24, change in activation energy and formation energy are tabulated for Ni-1 site and Ni-2 site substitutions. From these tables, it can be concluded that, for Ni-1 site substitution, AI, Co, Sb and Si increase activation energy for diffusion of La atom sharply. Except Co, these elements also decrease formation energy of the system. However, when formation energies for Ni-1 site and Ni-2 site are compared, it can be seen that, all of these elements prefer Ni-2 site on crystal structure because of the lower energy state. On the other hand, as can be seen on the Table 24, although AI, P, Sb, Si and Ti decreases formation energy of these system, all of the elements decrease also activation energy for diffusion of La atom which make diffusion of La atom easier.

From Table 23 and 24, it can be concluded that, effect of alloying on formation energy is more important than the effect on activation energy for diffusion of one La atom in the structure or certain elements are effective through the formation of a protective oxide layer, because it was known that some of the these elements such as AI, Si, Co and Ti increase cycle life of $LaNi_5$ [30,

34, 36], although they don't seem to be effective in diffusivity. They either form a protective oxide layer or decrease the formation energy of LaNi₅. In this manner, these elements actually prefer Ni-2 site substitution and decreases formation energy. Therefore, cycle life of LaNi₅ would be increased.

Figure 12. Activation energies for diffusion of La atom for La site substitution for Ca, Dy, Er, Gd, Sm, Y and Zr alloying elements.

Figure 13. Activation energies for diffusion of La atom for Ni-1csite substitution for Al, Co, Cu, Sb and Si alloying elements.

Figure 14. Activation energies for diffusion of La atom for Ni-2 site substitution for Al, Co, Cu, P, Sb, Si and Ti alloying elements.

CHAPTER 4

CONCLUSION

In this study, effects of alloying on CaNi₅ and LaNi₅ were studied using density functional theory within generalized approximation. In this regard, formation energies of the CaNi₅ and LaNi₅ compounds having different alloying elements were calculated for the understanding of the effect of the alloying element on the stability of the compound. It was found for CaNi₅ alloying that, all lanthanides and actinides and early transition metals (Sc, Y, Zr, Hf) replacing Ca and early transition metals (Sc, Ti, Zr, Hf) plus elements like Al, Si, P, Ge, Zn, Sn and Sb decrease the formation energy of CaNi5. In addition, effect of alloying on formation energy of hydride compounds of CaNi₅ were calculated and compared with the pure hydride compound. It was found that, although substitution of Ca with La, Ce and Yb do not change the formation energy of CaNi₅H₆ too much, other rare earth elements and Hf, Y and Zr decrease formation energy of CaNi₅H₆ between 4 % and 20 %. In addition, it was determined that, when Ni is substituted with Si, Ge and P decrease formation energy and Zr, Ti, Hf and Sn elements increase the formation energy of CaNi₅H₆. For LaNi₅ alloying, it was found that some lanthanides and actinides and early transition metals (Dy, Er, Gd, Sm, Th and Y) replacing La and for Ni replacing some early transition metals (Sc, Ti and Hf) plus elements like Al, Si, P, Ge, Zn, Sn, Pd, Au and Sb replacing Ni, decrease the formation energy of LaNi₅. Lower formation energy, compared to the pure compound, increases the stability which could improve the cyclic durability of CaNi5 and LaNi5 to be used as an anode in Ni-MH batteries. In addition, effect of alloying on volume expansion while hydrogen absorbing were investigated and it was found that some of the elements which decrease formation energy of CaNi₅, decrease also volume expansion while hydrogen absorbing. It can be concluded that these elements would be important to improve cycle life of CaNi₅

Secondly, in order to investigate effects of alloying on Ca diffusion in CaNi₅ and La diffusion in LaNi₅, activation energies of Ca and La diffusion for different alloys were calculated by Nudged Elastic Band method (NEB) method. Activation energy is important in order to investigate diffusion mechanism of Ca and La atom. According to found results for CaNi₅, for Ca site substitution, rare earth elements, Ti, Hf and Zr increase activation energy for diffusion of Ca atom. For Ni site substitution, Al, Fe, Si, Sn, V and Zn increase activation energy when

substituted with nickel atom on Ni-1 site. For LaNi₅, substitution of La atom with rare earth elements, Y and Zr increase activation energy for diffusion of La atom in the structure. For Ni site substitution, Al, Co, Sb and Si increase activation energy when substituted with Ni atom on Ni-1 site.

In this regard, effects of alloying was studied using an ab initio pseudo potential method. Therefore, it was determined that, low cycle life problem of CaNi₅ may be solved by proper alloying.
