

SYNTHESIS OF FIRST ROW TRANSITION METAL OXIDE NANOMATERIALS
FOR ELECTROCATALYTIC WATER OXIDATION REACTION

A THESIS SUBMITTED TO
THE GRADUATE SCHOOL OF NATURAL AND APPLIED SCIENCES
OF
MIDDLE EAST TECHNICAL UNIVERSITY

BY

ASUDE ÇETİN

IN PARTIAL FULFILLMENT OF THE REQUIREMENTS
FOR
THE DEGREE OF DOCTOR OF PHILOSOPHY
IN
CHEMISTRY

JANUARY 2020

Approval of the thesis:

**SYNTHESIS OF FIRST ROW TRANSITION METAL OXIDE
NANOMATERIALS FOR ELECTROCATALYTIC WATER OXIDATION
REACTION**

submitted by **ASUDE ÇETİN** in partial fulfillment of the requirements for the degree of **Doctor of Philosophy in Chemistry, Middle East Technical University** by,

Prof. Dr. Halil Kalıpçılar
Dean, Graduate School of **Natural and Applied Sciences**

Prof. Dr. Cihangir Tanyeli
Head of the Department, **Chemistry**

ABSTRACT

SYNTHESIS OF FIRST ROW TRANSITION METAL OXIDE NANOMATERIALS FOR ELECTROCATALYTIC WATER OXIDATION REACTION

Çetin, Asude
Doctor of Philosophy, Chemistry
Supervisor : Assoc. Prof. Dr. Emren Nalbant Esentürk

January 2020, 141 pages

Environmental concerns associated with the use of fossil fuels have elevated the demand for safe, clean and renewable energy sources. Hydrogen is an outstanding energy carrier because of the high amount of energy stored in its bond, and an excellent alternative to fossil fuels. Therefore, production of hydrogen from readily available and abundant sources such as water through electrochemical water splitting has gained increasing attention in the last couple of decades. However, water oxidation step of overall water splitting process has large energy barrier and thus, requires application of overpotential and use of highly stable and active catalysts for the efficient formation of hydrogen. A great number of nano-sized metal oxide materials have been proven to be very active catalysts for electrochemical water oxidation. In addition to their unique properties, their large surface area and thus, large active sites make such nanomaterials promising candidates as electrocatalysts. This dissertation covers the preparation and characterization of bimetallic oxide nanomaterials composed of various combinations of earth abundant, transition metals as well as their electrochemical activities towards water oxidation reaction.

Firstly, metal oxide nanomaterials in CuCr_2O_4 , FeMnO_3 , $\text{NiFe}_2\text{O}_4\text{-NiO}$ and $\text{NiCo}_2\text{O}_4\text{-NiO}$ structures with various morphologies were synthesized via simple and reproducible methods. Synthesized nanomaterials were then characterized using a combination of analytical techniques including XRD, SEM, EDX, TEM, XPS, ICP-OES and BET. Conductive electrode surfaces were modified with these nanomaterials, and finally their electrochemical behavior in water oxidation reaction were investigated. The overall water oxidation activity of the synthesized materials was observed to be comparable to benchmark RuO_2 or superior to some of the water oxidation catalysts having similar structures.

Keywords: Transition Metal Oxide, Nanomaterials, Water Oxidation, Oxygen Evolution, Electrocatalysis

Fosil yakıtların kullanımından kaynaklanan çevresel endişelerin artması güvenli, temiz ve yenilenebilir enerji kaynaklarına olan talebi önemli ölçüde artırmıştır. Hidrojen, bağında bulundurduğu yüksek enerji sebebiyle önde gelen enerji taşıyıcılarından. Aynı zamanda bu özelliğiyle fosil yakıtların kullanımına önemli bir alternatiftir. Bu sebeple, su gibi kolayca erişilebilen ve doğada bol miktarda bulunan kaynaklardan elektrokimyasal ayrıştırma yöntemiyle hidrojen elde edilmesi son yirmi yılda artan ilgi odağı haline gelmiştir. Fakat, suyun yükseltgenmesinin gerçekleştiği anot yarı tepkimesi yüksek enerji bariyeri sebebiyle suyun ayrışmasını yavaşlatmaktadır. Bu da, hidrojenin verimli bir şekilde elde edilebilmesi için aşırıgerilim uygulanmasını ve yüksek kararlılık ve etkinliğe sahip katalizörlerin kullanımını gerekli kılmaktadır. Çok sayıda metal oksit nanomalzeme suyun elektrokimyasal yükseltgenmesinde kullanılmış ve etkinlikleri kanıtlanmıştır. Benzersiz özelliklerinin yanı sıra, sahip oldukları geniş yüzey alanı ve dolayısıyla çok sayıdaki aktif yüzeyleriyle bu nanomalzemeler elektrokatalizör olarak gelecek vaat etmektedirler. Bu tez, doğada bol bulunan geçiş metalleri kullanılarak çeşitli

bileşimlerde bimetalik nanomalzemelerin hazırlanması ve tanımlanmasının yanı sıra suyun yükseltgenme tepkimesindeki elektrokimyasal etkinliklerinin incelenmesini kapsamaktadır. İlk olarak, farklı şekillere sahip CuCr_2O_4 , FeMnO_3 , $\text{NiFe}_2\text{O}_4\text{-NiO}$ and $\text{NiCo}_2\text{O}_4\text{-NiO}$ yapılarında nanomalzemeler kolay ve tekrarlanabilir yöntemlerle sentezlenmiştir. Sentezlenen nanomalzemeler XRD, SEM, EDX, TEM, XPS, ICP-OES ve BET gibi çeşitli analitik tekniklerle tanımlanmıştır. Daha sonra, iletken elektrot yüzeyleri bu nanomalzemelerle kaplanmış ve son olarak suyun yükseltgenme tepkimesinde elektrokimyasal etkinlikleri incelenmiştir. Sentezlenen malzemeler, bu tepkimede referans olarak kullanılan RuO_2 katalizörle kıyaslanabilir etkinlik göstermiştir. Bu malzemelerin benzer yapılarıdaki diğer katalizörlere kıyasla suyun yükseltgenmesinde daha aktif oldukları görülmüştür.

Anahtar Kelimeler: Geçiş Metal Oksitler, Nanomalzemeler, Suyun Yükseltgenmesi, Oksijen Salınımı, Elektrokataliz

To my beloved family,

ACKNOWLEDGMENTS

First and foremost, I owe my deepest and sincere gratitude to Assoc. Prof. Dr. Emren Nalbant Esentürk for giving me the opportunity to work in her research group and providing support, guidance and encouragement throughout my graduate studies. These eight years I have spent under her guidance have greatly inspired me not only in academic studies but also in many aspects of life. I am truly grateful and honored to have a chance to work with her.

I would like to express my sincere thanks to Prof. Dr. Ahmet Önal for his guidance and invaluable comments during the electrochemical studies. It would not be easy to come this far without his help and I am truly thankful for that.

I would like to thank my thesis monitoring committee members; Prof. Dr. Saim Özkar and Prof. Dr. Birgül Zümreoğlu Karan for their valuable comments and advices.

I would like to thank Prof. Dr. Ayşen Yılmaz for access to XRD instrument and her group members for their help during the measurements. Also, I would like to thank Central Laboratory of METU for their help during the characterization of my materials.

I would like to thank TUBITAK, Scientific and Technological Research Council of Turkey (Project No:117Z384) and TUBITAK Directorate of Science Fellowships and Grant Programmes (BİDEB), 2211 A- National Scholarship Programme for PhD for the financial support.

I would also like to thank all of my friends whom I had the chance to work with as teaching assistant. The time we spent together and the things I have learned from each and every one of them is truly valuable.

Also, I would like to express my thanks to all of the *NanoClusMate* Group members, both former and present, for their friendship. Among them, I would especially like

to thank Cansu Brban Bingl, İlkem Evcimen and Esra gn. Those years we were together in the laboratory were truly precious and I enjoyed every single moment of them.

I am greatly thankful to my dear friends Duygu Tan and Derya zhava, who are like sisters to me, for their unselfish moral support, friendship and for always being there for me whenever I needed.

Last but not least, my most heartfelt appreciation goes to my parents, Aydın etin and Rukiye etin. I am deeply grateful for their love, caring and constant support in the pursuit of my dreams and more importantly, for always believing in me.

CHAPTER 1

INTRODUCTION

The depletion of fossil fuels and environmental concerns associated with their extensive use have increased the demand for renewable, cheap, clean and safe energy sources significantly. Hydrogen, as an energy carrier is an outstanding alternative to fossil fuels or other risky sources such as nuclear energy. Moreover, hydrogen can be easily obtained from readily available and renewable sources such as water. Therefore, production of hydrogen, which is defined as the “sustainable fuel” of the future, through water splitting has gained well deserved attention and become focus of intensive research in the last couple of decades.

Production of hydrogen through electrochemical water splitting is particularly very attractive. However, water oxidation step occurring at the anode is considered as the bottleneck of overall water splitting. This is mostly because of the large energy barrier caused by the transfer of multiple electrons and protons during the reaction and thus, requires application of overpotential to overcome this energy barrier. Therefore, reducing the applied overpotential and increasing the rate of this reaction is critical in efficient production of hydrogen. Use of suitable catalysts is considered to be very effective in achieving this goal. Hence, designing new catalyst systems which can demonstrate high stability for multiple oxidation cycles and operate at low overpotential has become of utmost importance. Among the potential water oxidation electrocatalysts, metal oxides are one of the prominent choices in this demanding process. Particularly, nano-sized metal oxide particles, rods, wires or plates has drawn attention because of their high surface-to-volume ratio and thus, large surface area.¹⁻³

The most active and widely used metal oxide electrocatalysts are the oxides of precious and rare metals (i.e. RuO₂ and IrO₂). For instance, Liu et al. reported that

RuO₂ nanoparticles exhibited very good activity with an onset potential of 1.34 V (vs RHE) and a low overpotential of 190 mV to achieve current density of 10 mA cm⁻² (η_{10}).⁴ In addition, studies conducted by Sun et al. and Gao et al. exhibited very similar activities for RuO₂ nanomaterials. Both reports have shown that the onset potential was 1.48 V (vs RHE) for RuO₂ while slight differences in η_{10} was noted (325 mV⁵ and 347 mV²). Similar to their results, in our study too we have found that RuO₂ nanoparticles display good activity and determined the onset potential and η_{10} as 1.45 V (vs RHE) and 326 mV, respectively. Even though, RuO₂ and IrO₂ demonstrate high activity, their high cost, low availability and poor stability under alkaline conditions limit their practical use.⁶⁻¹⁰ Therefore, it is of great importance to prepare metal oxide nanocatalysts with high stability and efficiency using earth abundant and cheap transition metals.

Bimetallic materials in the form of perovskite or spinel have particularly attracted great deal of attention because of their rich chemistry caused by the contributions of both metals, very good stability and activity in alkaline medium.^{8,11-14}

Inspired by the Mn₄CaO₅ clusters in photosystem II, many catalyst systems composing of manganese have been developed. To illustrate, Kim et al. reported the synthesis and electrocatalytic activity of CaMnO₃ in perovskite structure for water oxidation in alkaline medium. Rotating disk electrodes (RDEs) modified with nanomaterial exhibited an onset potential of 1.6 V (vs RHE) and Tafel slope of 197 mV dec⁻¹. In addition, they have prepared oxygen-deficient Ca₂Mn₂O₅ perovskite material and studied its activity under the same conditions for comparison. The results reveal that with increased oxygen deficiency both onset potential (1.5 V vs RHE) and Tafel slope (149 mV dec⁻¹) decreased indicating improved water oxidation activity.¹⁵ Peng et al. demonstrated that upon doping with sulfur, CaMnO₃ nanotubes display better activity as electrocatalyst for water oxidation with higher stability. The onset potential was found as 1.6 V (vs RHE) while it was ca. 1.7 V (vs RHE) for pristine CaMnO₃. The observed enhanced activity was associated with the abundant active sites induced by oxygen vacancies due to sulfur replacement.¹⁶ Another study conducted by Du et al. exhibited the preparation of a series of nonstoichiometric

CaMnO_{3-δ} nanomaterials ($0 < \delta < 0.5$) and their water oxidation activities. The results show that CaMnO_{2.77} nanoparticles demonstrated the highest activity among the prepared nanomaterials with an onset potential of 1.4 V (vs RHE) and overpotential of 570 mV to generate current density of 4 mA cm⁻² (η_4).¹⁷

Perovskite structures having different metal combinations were also reported as water oxidation electrocatalysts. For instance, Jin et al. studied urchin-like La_{0.8}Sr_{0.2}MnO₃ materials and reported that the materials exhibit promising activities with onset potential and η_{10} of 1.57 V (vs RHE) and 985 mV.¹⁸ Studies conducted by Hua et al., on the other hand, showed that La_{0.8}Sr_{0.2}Mn_{0.9}Fe_{0.1}O_{3-δ} materials have lower η_{10} value (340 mV) compared to the one of reported by Jin et al.¹⁹ Moreover, various studies have reported that doping or coating the metal oxide nanomaterial with a non-metal can enhance its water oxidation activity. To illustrate, Xu et al. compared the electrocatalytic activities of both pristine and carbon-coated BaMnO₃ nanorods. The results showed that at the same overpotential value (i.e. 740 mV) observed current density increased significantly from 3 mA cm⁻² to 14 mA cm⁻² suggesting the improved conductivity upon coating with carbon.²⁰

Another widely used bimetallic oxide materials are the ones having spinel structures. In several studies, it was observed that bimetallic spinel oxides exhibit higher water oxidation activities compared to their monometallic counterparts. For instance, Yuan et al. have synthesized a series of tubular ferrite materials (MFe₂O₄, M: Fe, Co, Ni) and studied their activities by comparing overpotential values required to generate a current density of 10 mA cm⁻² (η_{10}). Fe₃O₄ nanotubes exhibited the lowest activity with η_{10} value of 432 mV, whereas NiFe₂O₄ and CoFe₂O₄ nanotubes required overpotentials of 340 and 392 mV to achieve the same current density value, respectively.²¹ Li et al. also studied a series of iron based catalysts for water oxidation. They prepared Fe₂O₃ and MFe₂O₄ (M: Mn, Co, Ni, Cu) nanoparticles by electrospinning and investigated their activities.²² Similar to the work of Yuan et al, in this study too, monometallic Fe₂O₃ nanoparticles exhibited the lowest activity with an onset potential of 1.79 V (vs RHE) and η_5 of 750 mV, while much lower onset potentials and overpotential were obtained for MnFe₂O₄ (1.72 V vs RHE, η_5 : 640

mV), CoFe_2O_4 (1.67 V vs RHE, η_5 : 520 mV), CuFe_2O_4 (1.71 V vs RHE, η_5 : 540 mV) and NiFe_2O_4 (1.70 V vs RHE, η_5 : 550 mV). In addition, nanofibers of the same structures were also prepared and activities were tested for water oxidation for comparison. Each of the fibers displayed higher catalytic activities with lower onset potentials and overpotentials than their nanoparticle counterparts. Observed activity was attributed to the larger surface area of the nanofibers which allows more contact sites between the catalyst and the substrate.²²

Among transition-metal based spinel oxides, NiCo_2O_4 is also subjected to considerable attention owing to its rich redox chemistry caused by the contributions of both cobalt and nickel ions. In addition, recent studies have shown that NiCo_2O_4 exhibits higher electrical conductivity and thus, enhances electrochemical activity than its monometallic counterparts (NiO and Co_3O_4).²³ Barauskiene and Valatka have reported the preparation of NiCo_2O_4 nanomaterials on stainless steel by electrodeposition and investigated its activity towards water oxidation reaction. They concluded that the prepared nanomaterial has comparable activity to that of benchmark IrO_2 with an onset potential of 1.6 V (vs RHE) and η_{10} of 530 mV.²⁴ On the other hand, Zhao et al. reported a slightly higher onset potential of 1.63 V (vs RHE) with lower η_{10} (440 mV) for NiCo_2O_4 nanomaterials.²⁵ NiCo_2O_4 nanomaterials were also prepared in wire morphology and tested for electrocatalytic water oxidation. According to the studies by Peng et al. NiCo_2O_4 nanowires exhibited good activity with low onset potential of 1.56 V (vs RHE).²⁶ Nanowires prepared by Yu et al. also demonstrated low overpotential value of η_{10} : 460 mV.²⁷ On the other hand, Su et al. reported NiCo_2O_4 nanowire arrays having superior water oxidation activity. The overpotential required to achieve current density of 10 mA cm^{-2} was determined as 350 mV with use of much smaller catalyst loading (0.2 mg cm^{-2}) compared to the one reported by Yu et al. (1.0 mg cm^{-2}).²⁸

Furthermore, recent studies have revealed that co-presence of NiO and NiCo_2O_4 or NiFe_2O_4 boosts each other's activity significantly because their close interaction promotes better charge transfer. There are several literature reports on the synthesis and electrocatalytic activities for water oxidation reaction of such heterostructures.

Mahala and Basu prepared both NiCo₂O₄ and NiO/NiCo₂O₄ nanosheets and compared their electrocatalytic activities. Biphasic NiO/NiCo₂O₄ nanosheets exhibited higher catalytic performance with much lower onset potential (1.59 V vs RHE), overpotential (η_{10} : 360 mV) and Tafel slope (61 mV dec⁻¹) than that of NiCo₂O₄ (Onset: 1.66 V vs RHE, η_{10} : 430 mV, Tafel slope: 139 mV dec⁻¹).²⁹ Liu et al. also performed a similar study by using NiFe₂O₄ and NiO/NiFe₂O₄ nanorods. The onset potential and η_{10} for NiFe₂O₄ nanorods were found as 1.55 V (vs RHE) and 370 mV, respectively. On the other hand, NiO/NiFe₂O₄ heterostructure demonstrated enhanced performance with an onset potential of 1.46 V (vs RHE) and η_{10} of 302 mV.^{30,31}

In the light of these information, this dissertation aims to synthesize bimetallic oxide catalyst systems composing of earth abundant, first row transition metals in the nano regime and study their electrochemical activities towards water oxidation reaction. Preparation of the nanomaterials were achieved by two facile solution-phase methods, namely sol-gel and hydrothermal synthesis. Obtained nanomaterials were then characterized by several analytical techniques. After characterization, electrode surfaces such as fluorinated tin oxide (FTO) and glassy carbon (GC) were modified with synthesized nanomaterials and their performance in water oxidation reaction were investigated using electrochemical techniques. Prepared transition metal oxide nanomaterials were found to be stable catalysts in electrochemical water oxidation. Furthermore, activities of the catalysts were observed to be comparable to that of water oxidation catalysts with similar structures.

CHAPTER 2

TRANSITION METAL OXIDES

2.1 General Introduction

The binary compounds of oxygen with transition metals constitute one of the most intriguing groups of materials due to their facile synthesis, stability and diverse composition and structure. In addition, ability of transition metals to have multiple oxidation states leads to a great number of compounds with tunable properties such as thermal, electrical, magnetic and optical properties for specific applications. Such diversity of transition metal oxides (TMOs) stems from the partially filled d-orbitals of the metal and the interactions between electrons in these orbitals.^{32,33}

TMOs are formed by electron transfer between less electronegative transition metal atoms and more electronegative oxygen atoms. Depending on the number of electrons lost in their d-orbitals, transition metals can form a wide range of oxides from monoxides (e.g NiO), dioxides (e.g RuO₂), to higher and complex oxides (e.g WO₃, LaMnO₃, NiCo₂O₄). Each of these oxides embodies different bonding and crystal structures. Hence, it is necessary to apprehend the crystal chemistry of TMOs in order to better interpret their behavior in certain applications.

2.2 Classification and Crystal Structures of Transition Metal Oxides

TMOs crystallize in many structures namely, rock salt, wurtzite, rutile, ReO₃, perovskite, spinel and corundum-type. Common feature of these structures is that larger oxide ions are arranged in either cubic or hexagonal close-packed arrays, which leads to formation of octahedral and tetrahedral networks while the smaller transition metal ions occupy the holes created by these oxide networks.

2.2.1 Monoxides

All of the first row transition metals, except scandium and chromium, form *monoxides*. Five of the second row transition metals (zirconium, niobium, palladium, silver and cadmium) along with mercury of third row transition metals form monoxides as well. Most of them crystallize in *rock salt* structure in which oxide ions form cubic close packing (ccp) array and the transition metal ions occupy all of the octahedral holes (Figure 2.1). Alternatively, this structure can be described as being composed of corner-sharing octahedral MO_6 units with (6,6)-coordination.^{32,33}

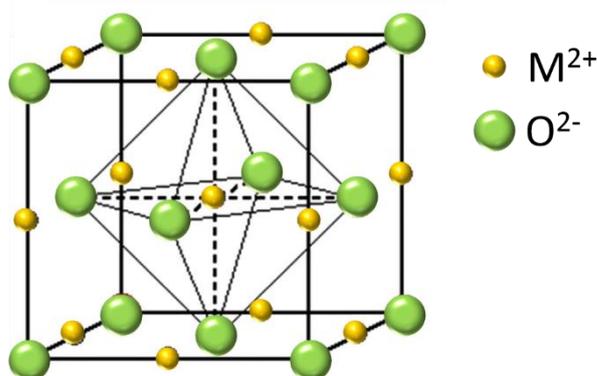

Figure 2.1. Unit cell of rock salt structure (green circles: oxygen atoms, yellow circles: transition metal atoms)

In some cases, nonstoichiometry, atom deficiency or relocation of atoms from their ideal positions can result in deviations in TMOs. Some of these monoxides, such as ZnO, adopt *wurtzite* structure. Wurtzite structure comprise of hexagonal close packing (hcp) arrays of oxide ions with transition metal ions located in half of the tetrahedral cavities (Figure 2.2). Each ion is surrounded by four counter ion leading to (4,4)-coordination.^{32,33}

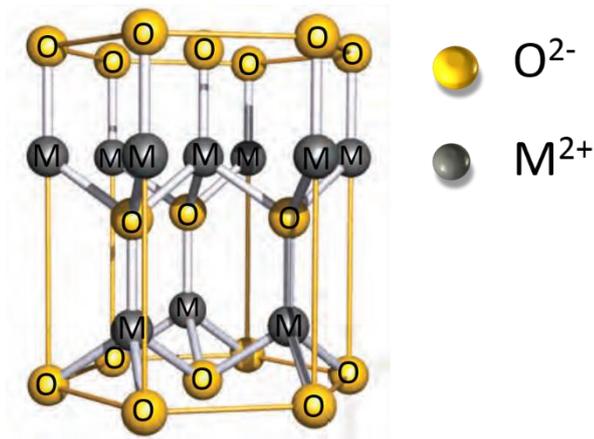

Figure 2.2. Unit cell of wurtzite structure (yellow circles: oxygen atoms, grey circles: transition metal atoms) (modified from ³⁴)

2.2.2 Dioxides

Dioxides are formed by titanium, vanadium, chromium and manganese of first row transition metals. In addition, almost all of the second and third row transition metals, except cadmium form dioxides. These TMOs assume either *rutile* or *fluorite* crystal structures. The rutile structure is made up of hcp arrays of oxide ions (Figure 2.3). Ideally, in this structure, half of the octahedral holes are occupied by the transition metal ions while the tetrahedral holes are empty. Each transition metal ion is surrounded by six oxygen and each oxygen is surrounded by three metal ion, resulting in (6,3)-coordination.^{32,33}

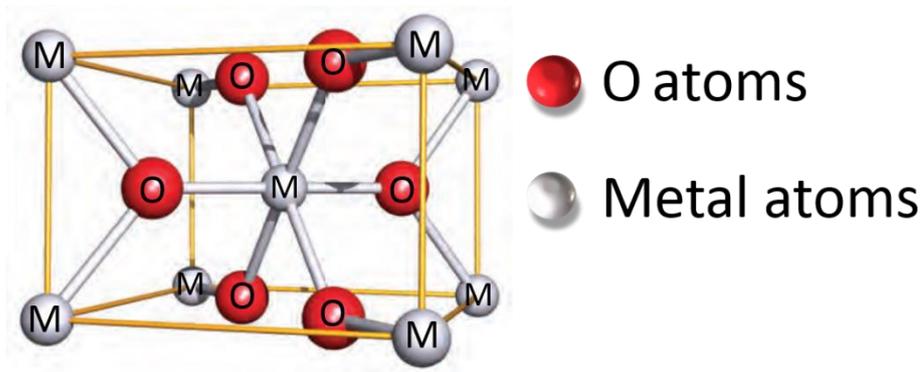

Figure 2.3. Unit cell of rutile structure (red circles: oxygen atoms, pale grey circles: transition metal atoms) (modified from³⁴)

Figure 2.4 shows the fluorite structure. As opposed to other structures, transition metal ions arrange in ccp arrays while oxide ions occupy all of the tetrahedral holes forming a lattice with (8,4)-coordination.

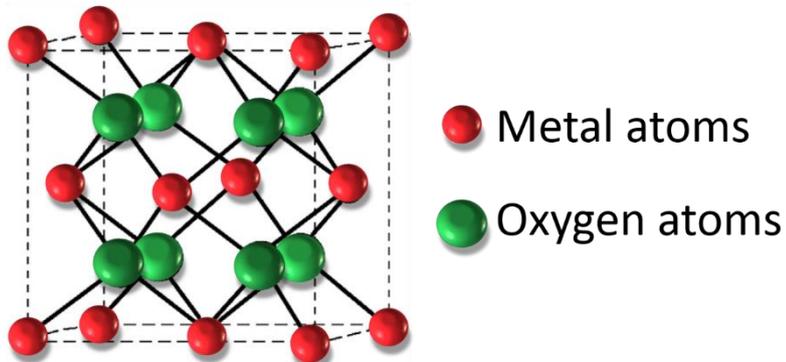

Figure 2.4. Unit cell of fluorite structure (green circles: oxygen atoms, red circles: transition metal atoms)

2.2.3 Sesquioxides – corundum type

Most of the first row transition metals in their +3 oxidation state, except zinc, crystallize in *corundum-type structure* (M_2O_3). In this structure, the transition metal ions (M^{3+}) are located in two-third of the octahedral cavities which are formed by hcp arrangement of oxide ions (Figure 2.5) giving rise to a (6,4)-coordination.³²

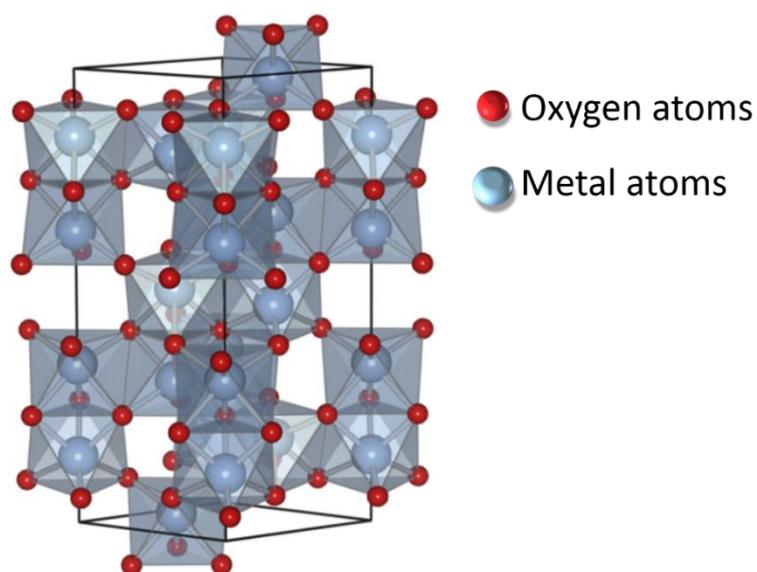

Figure 2.5. Corundum structure of TMOs (M_2O_3) (red circles: oxygen atoms, blue circle: transition metal atoms occupying the octahedral cavity formed by O^{2-} ions) (modified from³²)

2.2.4 Trioxides

Transition metals forming *trioxides* are rare due to the requirement of +6 oxidation state. Molybdenum, rhenium and tungsten are the only transition metals that show MO_3 stoichiometry. These oxides adopt rhenium trioxide structure which consist of cubic unit cell with Re ions at the corners and oxide ions at the edge-centers (Figure 2.6). Alternatively, the structure can be viewed as being made up of corner-sharing

ReO₆ octahedra. Molybdenum trioxide (MoO₃) has a layer structure which is composed of chains formed by corner sharing MoO₆ octahedral units. These two chains are attached to each other by sharing adjacent edges of the octahedra resulting in a double layer. In WO₃, slightly distorted WO₆ units are connected by corner sharing.³²

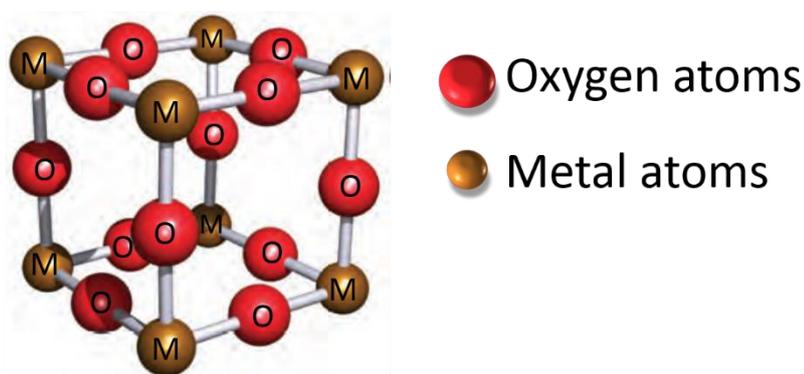

Figure 2.6. Unit cell of ReO₃ structure (red circles: oxygen atoms, gold circles: transition metal atoms) (modified from³⁴)

2.2.5 Spinels

TMO *spinels* generally have the AB₂O₄ composition, where A and B are metal ions. The spinel structure is formed by ccp array of oxide ions in which A cations fill one-eighth of the tetrahedral voids and the B cations fill half of the octahedral voids (Figure 2.7). In order to maintain charge neutrality, cation A and B can have oxidation states of either +2 and +3 (A²⁺B₂³⁺O₄²⁻) or +4 and +2 (A⁴⁺B₂²⁺O₄²⁻), respectively⁸.

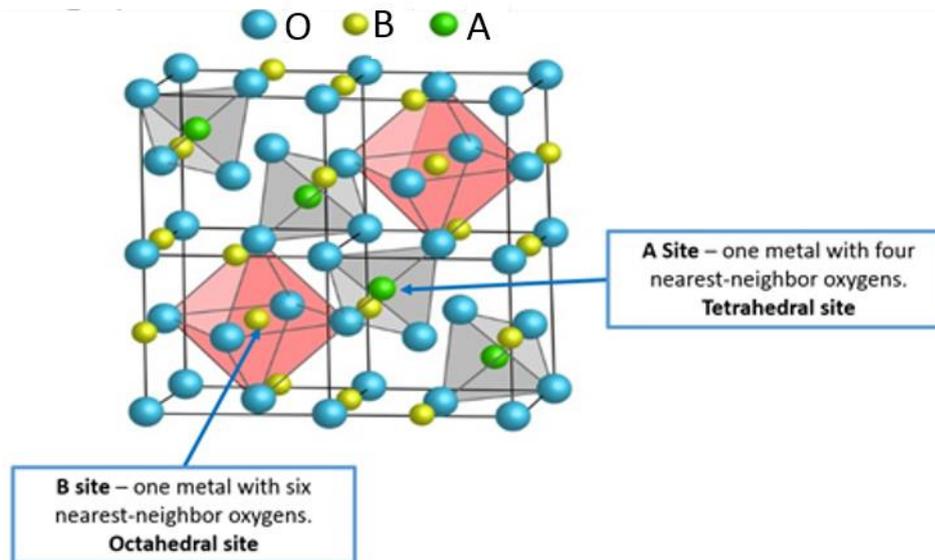

Figure 2.7. Unit cell of spinel structure (green circles: A cations, yellow circles: B cations and blue circles: oxygen atoms)

Depending on the cation distribution in tetrahedral and octahedral holes, spinels can be categorized into three types, namely normal, inverse and complex spinels. Zhao et al suggested the following representation of spinels, $A_{1-\lambda}B_{\lambda}[A_{\lambda}B_{2-\lambda}]O_4$, in order to identify them easily. In this notation, $[A_{\lambda}B_{2-\lambda}]$ represent the metal ions occupying octahedral holes while the ions before square brackets, $A_{1-\lambda}B_{\lambda}$, represent the ones located in tetrahedral holes. When $\lambda = 0$, the structure is defined as *normal spinel* ($A[B_2]O_4$) with A^{2+} and B^{3+} ions located in tetrahedral and octahedral holes, respectively. $\lambda = 1$ leads to *inverse spinel* structure which can be denoted as $B[AB]O_4$. In inverse spinel, A^{2+} ions occupy the octahedral sites while B^{3+} ions are equally distributed in octahedral and tetrahedral sites. In the case of $0 < \lambda < 1$, the structure is complex spinel. Complex spinels have mixed metal ion distribution in octahedral and tetrahedral sites. In this regard, they are considered as being intermediate between normal and inverse spinels.⁸

Distribution of metal ions in spinel structures is governed by several factors namely, radius of the metal, electrostatic interactions between ions and the crystal field

stabilization energy (CFSE) difference between octahedral and tetrahedral fields of the metal ions. This energy difference, also named as octahedral site preference energy (OSPE), has a significant effect on the structure adopted by the TMOs. For instance, Mn_3O_4 has a normal spinel structure since Mn^{3+} ion can acquire higher CFSE occupying octahedral interstices. Hence, Mn^{2+} ions occupy tetrahedral interstices giving rise to $\text{Mn}^{2+}[\text{Mn}_2^{3+}]\text{O}_4$ configuration. On the other hand, Fe^{2+} ions rather than Fe^{3+} ions in Fe_3O_4 strongly prefer to fill octahedral holes because of their greater CFSE in octahedral field. Thus, Fe_3O_4 is inverse spinel with $\text{Fe}^{3+}[\text{Fe}^{2+}\text{Fe}^{3+}]\text{O}_4$ configuration.^{8,32,33}

2.2.6 Perovskite

Perovskite structure, generally denoted as ABO_3 , is based on ReO_3 structure. Corner sharing octahedral BO_6 units are arranged in cubic network, and A cations occupy the 12-coordinate hole created by these octahedra (Figure 2.8). The structure can also be described as A cation located in the center of a cube formed by the B cations, whereas oxide ions reside in the edge centers of the cube.

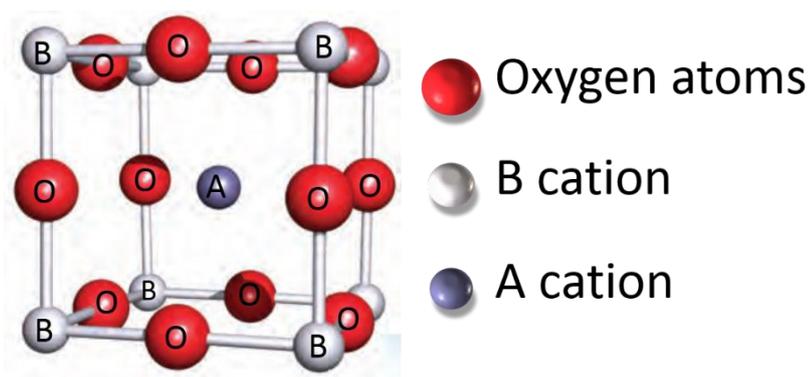

Figure 2.8. Unit cell of perovskite (ABO_3) structure (red circles: oxygen atoms, purple circle: A cation and pale grey circles: B cations) (modified from³⁴)

In perovskite structure, A and B cations can bear different charge distributions in order to achieve charge neutrality; $A^{1+}B^{5+}O_3$ (e.g. $NaWO_3$), $A^{2+}B^{4+}O_3$ (e.g. $CaTiO_3$) and $A^{3+}B^{3+}O_3$ (e.g. $LaCoO_3$). Generally, A ions are alkali, alkaline earth or lanthanide ions while B are transition metals ions.^{32,33,35}

2.3 Preparation of Transition Metal Oxide Nanomaterials

Materials in the nano regime have attracted considerable attention owing to their unique properties and viability in numerous applications. The exciting properties of the nanomaterials, which can be altered to suit certain applications, have motivated researchers to explore new synthetic approaches to prepare such materials. Consequently, many different methods have been employed and made it possible to obtain nanomaterials with a wide range of unique morphologies, crystal structures and compositions.

Transition metal oxide nanomaterials can be prepared by two basic approaches, namely *top-down* (physical methods) and *bottom-up* (physical and chemical methods). Top-down method includes the miniaturization of the large scale material by lithography or other related techniques. However, high cost, irregular and rough features obtained on atomic scale and irreproducibility restrict the use of this method in the preparation of nanomaterials.³⁶ On the other hand, bottom-up approach consist of assembling atoms or molecules to generate large scale materials. Bottom-up approach also has the advantage of control over crystallite size and/or shape by use of atoms, molecules or individual nanoparticles as building blocks.³⁶ Moreover, this technique includes a wide variety of methods ranging from solid-phase synthesis (e.g. flux growth, thermal decomposition, pulsed laser ablation/deposition) to solution-phase (e.g. coprecipitation, polyol, microemulsion, sol-gel, hydrothermal/solvothermal) and vapor-phase synthesis (e.g. chemical vapor deposition, spray pyrolysis, magnetron sputtering).⁸

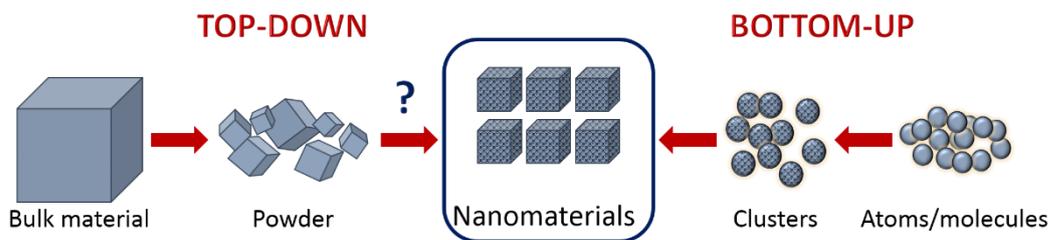

Figure 2.9. Top-down and bottom-up approaches used to obtain nanomaterials

Among all these methods, solution-phase synthesis has several advantages over solid- or gas-phase methods. It provides control over the reaction pathways which enables synthesis of nanomaterials with distinct crystal structures. In addition, nanoparticles having uniform size distribution, homogeneous compositions and morphologies can be obtained by utilizing solution-phase synthesis.³⁶ The most common synthetic routes used in the solution-phase preparation of TMO nanomaterials are sol-gel and hydrothermal/solvothermal methods and the details of these techniques are explained in the following sections.

2.3.1 Sol-Gel Method

Sol-gel process is one of the most facile methods for the synthesis of metal oxide materials, most commonly as nanoparticles. It can be defined as inorganic polymerization of precursors to yield inorganic solids (Figure 2.10).^{8,36,37} A typical sol-gel synthesis consists of the following steps:

- i) *Formation of sol* by dissolution of the precursors together with a suitable reagent in a solvent. Mostly, metal salts or metal alkoxides are used as precursors. Citric acid, propionic acid and ethylene glycol are generally added as chelating agents. After dissolution, precursors are hydrolyzed to yield hydroxides/monomers followed by a condensation step to form oligomers.

- ii) *Formation of gel* by further condensation of the monomers/oligomers. In this step, due to hydrogen bonding between the solvent and the gel, the oxide material consists of porous structure.
- iii) *Aging*: In this step, condensation of the gel continues and it solidifies. In order to increase the rate of aging process, it can be done by heating the obtained gel.
- iv) *Drying*: Drying process can be done either by supercritical drying, which results in the formation of aerogel with high porosity in the structure or by thermal evaporation leading to xerogel formation with smaller pore size compared to that of aerogel.
- v) *Dehydration*: In this step, -OH groups present on the surface and organic moieties are removed by thermal treatment at elevated temperatures.

- Metal precursors
- Complexing agent (e.g. citric acid)
- Water

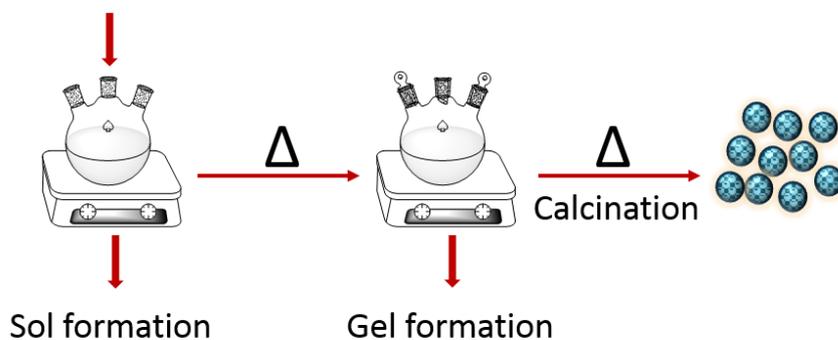

Figure 2.10. Schematic representation of sol-gel synthesis of nanomaterials

2.3.2 Hydrothermal / Solvothermal Method

Hydrothermal method is defined as high-pressure solution-phase synthesis in which the solvent is water. As an alternative to water, other solvents such as ethanol, 2-propanol or ethylene glycol can also be used, and this method is referred to as *solvothermal* synthesis.⁸ In this method, autoclaves which can tolerate high temperature and pressure are used as reaction vessels.

This method is one of the most commonly used techniques for the synthesis of TMO nanomaterials having a wide variety of morphologies. The working principle is that upon heating the mixture in the autoclave, regions having two different temperatures are created. The precursors are dissolved in the hotter region which resides in the lower part of the vessel. Then, this solution ascends to the upper part while the cooler part of the solution settles down. As the temperature of the upper part is reduced, the solution becomes supersaturated and crystal formation occurs.³⁷

Nanomaterials with controlled size and composition can be obtained easily by modifying the reaction temperature and/or solvent used. In addition, with the utilization of different type of surfactants such as cetyltrimethylammonium bromide (CTAB), cetyl alcohol, urea or nitrilotriacetic acid (NTA) well-dispersed nanomaterials having various morphologies can be prepared.⁸

- Metal precursors
- Surfactant (e.g. urea, NTA, CTAC)
- Water

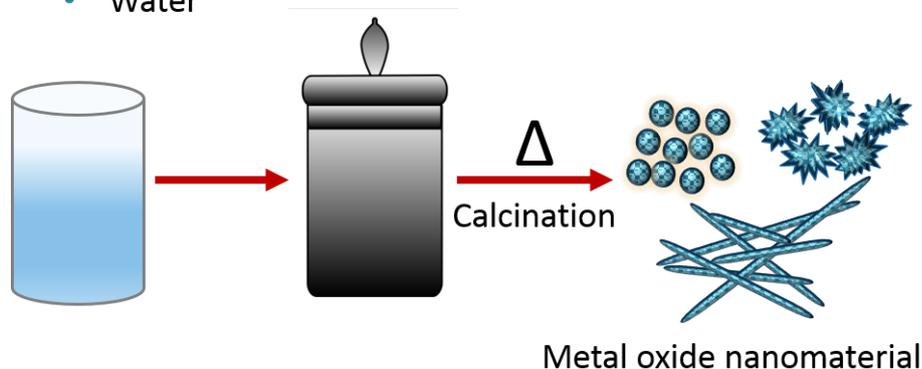

Figure 2.11. Schematic representation of hydrothermal synthesis of nanomaterials

2.4 Characterization of Transition Metal Oxide Nanomaterials

Characterization of TMO nanomaterials is as essential as preparing them with desired properties in nanoparticle research area. In order to gain valuable insights on their behavior in certain applications, one must analyze the composition, structure and morphology of the nanomaterials. Several analytical techniques can be utilized for characterization of nanomaterials.

The most common technique used is electron microscopy. *Scanning electron microscopy* (SEM) provides information about surface topography of nanoparticles by analyzing either secondary or back-scattered electrons. However, SEM does not give data on atomic scale since its resolution is ca. 5 nm. Therefore, *transmission electron microscopy* (TEM) is used in order obtain detailed information about size, shape and composition of nanoparticles and their distribution. In addition, with utilization of *high resolution TEM* (HR-TEM), diffraction patterns and lattice spacing of the nanoparticles can be obtained. *Energy dispersive x-ray spectroscopy* (EDX) can also be studied in conjunction with both SEM and TEM, which provides primitive elemental analysis of the sample.

X-Ray diffraction (XRD) is another valuable technique applied to characterize nanoparticles. Analysis of crystal structure and chemical composition of nanomaterials as well as phase of the bulk structure are possible by XRD. Moreover, the characteristic set of lattice spacings obtained from x-ray pattern can be useful for identifying the material. Determination of crystallite size of the nanomaterials is also possible with utilization of Debye-Scherrer equation (2.1).³⁸

$$\tau = \frac{K \lambda}{\beta \cos \theta} \quad (2.1)$$

where τ is the average crystallite size, K is a dimensionless shape factor (0.9), λ is the X-ray wavelength (nm), β is the line broadening (radian) at full width half maximum (FWHM) and θ is the Bragg angle.

X-Ray photoelectron spectroscopy (XPS) is utilized to investigate surface properties of the nanoparticles. Photoelectrons emitted from the surface have characteristic energy levels, which reveal the chemical and electronic state of the elements present in the material as well as their concentration and distribution across the surface. Therefore, XPS is a very useful tool for both qualitative and quantitative evaluation of surface structure of nanoparticles.

Adsorption-desorption techniques are frequently employed to acquire information about surface area, pore volume and pore size of the nanomaterials. Additionally, porosity of the materials (i.e. microporous, mesoporous or macroporous) can be determined from the obtained adsorption-desorption isotherms.

Moreover, elemental analysis techniques such as inductively coupled optical emission spectroscopy (ICP-OES), infrared spectroscopy (IR), Raman spectroscopy and scanning tunneling microscopy (STM) are other techniques that are used commonly in the characterization of nanomaterials.

CHAPTER 3

WATER SPLITTING

Concerns regarding the energy crisis that may arise in the future have led researches focus on finding and developing new energy sources. When the effect of greenhouse gases released due to extensive use of fossil fuels is taken into consideration, alternative energy sources which are environmentally sustainable and have the potential of widespread use have gained increasing attention.³⁹⁻⁴³ In this context, renewable energy sources are particularly promising. However, in order to be used on a global scale, there are a number of problems that need to be considered.⁴⁴ Foremost is the lack of reliable methods of storing the energy generated from these sources including solar and wind. In order to overcome this problem, research has focused on storing the energy in the chemical bonds of a suitable fuel.⁴⁵

Hydrogen, as an energy carrier, has become focus of increasing attention owing to the high energy stored in its bonds. Moreover, it serves the possibility to be obtained from readily available, abundant and renewable energy sources such as water. Water splitting in which electrons and protons are extracted is a well-known process for hydrogen generation (summarized by the following reactions).⁴⁶

Water splitting, especially *water oxidation*, is both thermodynamically and kinetically a demanding process (non-spontaneous, $\Delta G^\circ = 475$ kJ/mol) and needs high energy to occur. To overcome this difficulty, use of suitable catalysts is required. In nature, oxygen evolution center located in photosystem II in plants is

known to be highly efficient and extensively studied catalyst in water oxidation reaction. In this center, oxidation process occurs in the Mn_4CaO_5 clusters. Inspired by this structure in nature, research has focused on synthesis of stable and highly active catalysts. Thus, developing novel catalysts containing transition metals with higher performance for water oxidation has become very active research area.⁴⁷

Water oxidation can be studied by three methods, namely chemical, photoelectrochemical and electrochemical oxidation. The details of these techniques are explained in the following sections.

3.1 Chemical Water Oxidation

Chemical water oxidation involves the use of sacrificial reagents. In this method, transition metals are oxidized (activated) by sacrificial reagents. Then, activated metals oxidize water to produce oxygen. Hypochlorite (ClO^-), peroxomonosulfate (HSO_5^-), sodium periodate (NaIO_4), cerium ammonium nitrate ($\text{NH}_4\text{Ce}(\text{NO}_3)_4$, CAN), $[\text{Ru}(\text{bpy})_3]^{3+}$ (bpy: 2,2'-bipyridine) are commonly used examples of sacrificial reagents in water oxidation. Although chemical oxidation provides information on catalyst performance in a simple and rapid way, there are some limiting factors. Sacrificial reagents are consumed irreversibly during the reaction; therefore, it brings out the possibility that oxygen produced may contain one oxygen atom from this reagent. In addition, sacrificial reagents cause the catalyst to decompose, resulting in depletion of catalyst activity and/or transformation of the catalyst to another material.^{48,49} Since sacrificial reagents are used in larger amount compared to the catalyst, they affect the catalyst stability and thus, cause misinterpretation of the experimental results.

3.2 Photoelectrochemical Water Oxidation

In this method, catalysts are activated via light which later oxidize water. Metal-semiconductor composites (i.e Pt/TiO_2) can be used as catalysts in which

semiconductor component is the photocatalyst while metal one is the co-catalyst.⁴⁸ When exposed to light with energy higher than its band gap ($h\nu > E_{\text{gap}}$), an electron is ejected from the valence band (V.B.) of the photocatalyst and migrates to the conduction band (C.B.) forming an electron-hole pair. Then, water adsorbed on the positively charged holes is oxidized while protons are reduced by the electrons transferred to the co-catalyst. In addition to metal-semiconductor composites, three component system which includes a photosensitizer (i.e. $[\text{Ru}(\text{bpy})_3]^{3+}$), a molecular catalyst and a sacrificial electron acceptor (i.e. $\text{S}_2\text{O}_8^{2-}$, $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$, $[\text{Co}(\text{bpy})_3]^{3+}$, $[\text{Co}(\text{phen})_3]^{3+}$ (phen:phenanthroline)) can be used in photochemical water oxidation. Once the photosensitizer is excited with light, electron transfer occurs to sacrificial electron acceptor. Oxidized photosensitizer then activates the catalyst and thus, catalytic cycle is initiated. However, due to the reactive singlet oxygen produced during the process, stability of the photosensitizer is affected.⁴⁶

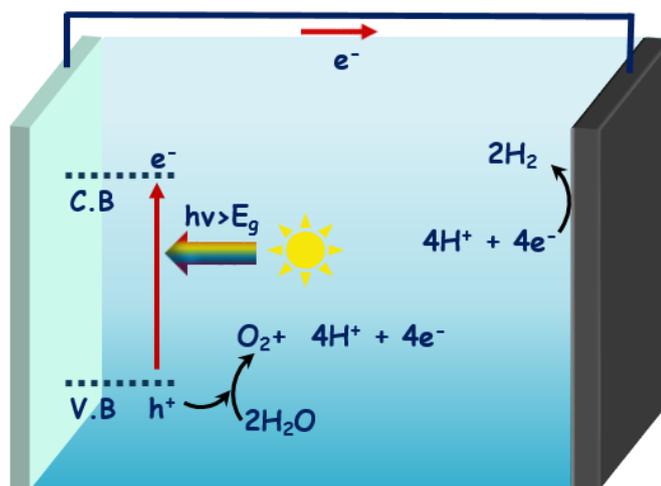

Figure 3.1. Schematic representation of photoelectrochemical water oxidation

3.3 Electrochemical Water Oxidation

In addition to chemical and photochemical methods, water oxidation can be studied via electrochemical oxidation. In this method, catalysts are used as anode materials. Catalysts are oxidized with the applied potential. Then, the activated catalyst causes water molecules to oxidize. The most significant advantage of electrochemical oxidation is that the system being studied shows resemblance to conditions of solar fuel generation cell.⁴⁹ This provides a practical way to analyze the activities of systems which will be used in photochemical and/or electrophotochemical water oxidation. Therefore, stable catalysts which are proven to be efficient through electrochemical oxidation are considered as important prototypes for the ones to be developed for solar fuel generation cells.

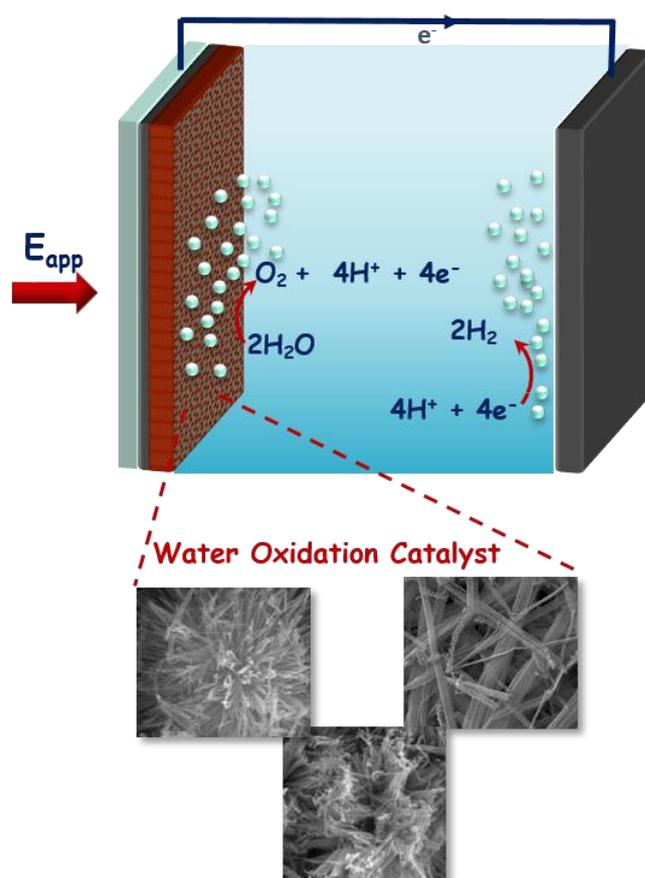

Figure 3.2. Schematic representation of electrochemical water oxidation

Water splitting is a non-spontaneous process and needs high energy because, 4 O-H bonds are cleaved for the formation of O-O bond. Therefore, water oxidation requires not only use of stable catalysts but also application of overpotential. The amount of overpotential applied is crucial for the net energy obtained from the reaction. Hence, developing catalyst which requires minimum amount of overpotential in water oxidation has become focus of this research area.

3.4 Evaluation of Water Oxidation Activity of an Electrocatalyst

The important parameters in the evaluation of water oxidation activity of a catalyst include onset potential, overpotential, Tafel slope, capacitance and stability. Several electrochemical techniques can be employed in order to determine these parameters such as linear sweep voltammetry (LSV), cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS), chronoamperometry, chronopotentiometry and/or controlled potential coulometry.

- i) *Polarization curves*: Polarization curves can be obtained by recording linear sweep voltammograms of an electrode modified with catalyst. These curves provide three important data about catalysts' activity. First one is the *onset potential*. Onset potential indicates the start of water oxidation and usually refers to the potential at a current density of $10 \mu\text{A cm}^{-2}$.⁸ It can also be determined by drawing two tangent lines; one at non-faradaic region and the other at faradaic region where increase in current density is observed. The intersection point of these two tangent lines results in onset potential (Figure 3.3).⁵⁰

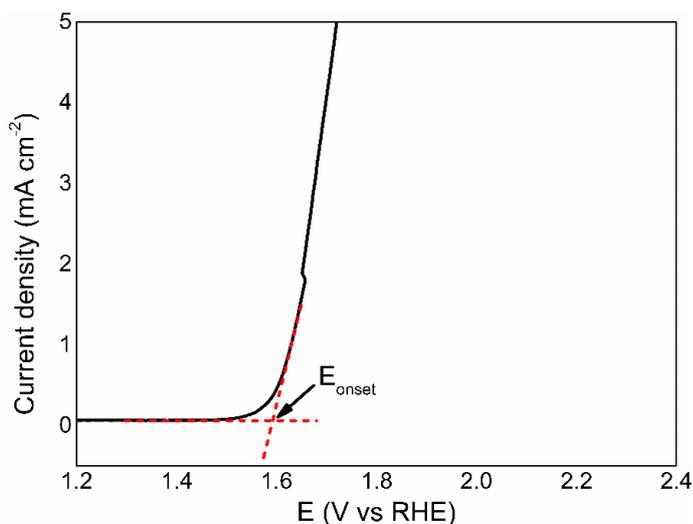

Figure 3.3. Determination of onset potential from a polarization curve

Secondly, overpotential values can also be determined from polarization curves. Ideally, the applied potential for a reaction to occur should be equal to the equilibrium potential of that reaction. However, higher potential than that of equilibrium potential is applied to surpass the kinetic barrier of the reaction.⁶ This difference between the applied potential and equilibrium potential is defined as overpotential and it can be expressed by the following equation (3.4) where E is the applied potential and E_{eq} is the potential under equilibrium conditions.

$$\eta = E - E_{eq} \quad (3.4)$$

In addition to onset potential and overpotential, Tafel slope can also be determined. In order to find Tafel slope, linear portion of polarization curves are fitted to Tafel equation (3.5) where η is the overpotential, a , j and b are intercept to find exchange current density and Tafel slope, respectively).

$$\eta = a + b \cdot \log(j) \quad (3.5)$$

The value of Tafel slope presents valuable insights about the mechanism and rate determining step of the overall reaction.^{6,8}

Lower onset potential and overpotential are indications of an efficient electrocatalyst while lower Tafel slope implies faster water oxidation kinetics.

- ii) *Capacitance:* Catalysts on electrode surface can act as capacitor by forming a double-layer between electrolyte and catalyst film and accumulating charge. Double-layer capacitance (C_{dl}) is directly proportional to the active surface area of the modified electrode, which gives information about the number of atoms that can act as a catalyst. The value of C_{dl} can be determined by measuring CV in a non-faradaic potential window and at various scan rates (v). The measured current is assumed to be due to double-layer charging current (i_{dl}) having the following relation (equation (3.6)).⁸

$$C_{dl} = \frac{i_{dl}}{v} \quad (3.6)$$

The plot of i_{dl} versus v results in a straight line whose slope yield C_{dl} values of the catalysts. Electrochemically active surface area (ECSA) and roughness factor (RF) of the catalysts, which are also important parameters in the assessment of catalyst activity can be determined by equation (3.7) and (3.8), respectively.

$$ECSA = \frac{C_{dl}}{C_s} \quad (3.7)$$

where C_s is the specific capacitance of the material.

$$RF = \frac{ECSA}{GSA} \quad (3.8)$$

where GSA is the geometric surface area of the electrode.

Higher C_{dl} , ECSA and RF values signify the presence of large number of active sites, and thus improved catalytic performance.

- iii) *Stability:* Stability of an electrocatalyst can be assessed by applying a constant potential to electrode for a long period of time. The variation in current density with time can be monitored during the long-term electrolysis. Another way is recording polarization curves before and after electrolysis in order to compare the onset potential, overpotential or

current densities. A small or no change in these parameters implies high stability of the electrocatalyst.

3.5 Motivation of the Dissertation

Together with the recent advances in technology, demand for cheap, renewable and environmentally benign energy sources in order to satisfy the energy need of the world has elevated greatly. Therefore, research on finding abundant sources that can be used in energy production has become of utmost importance. Among all, role of hydrogen, which is obtained through water splitting, in energy production has earned great deal of attention. However, water oxidation, which is one of the half reactions of water splitting, is an electrochemically difficult and energetically demanding process. Hence, this reaction limits the overall water splitting. As a result, designing and preparing catalyst systems that increase the rate of water oxidation reaction has become an active research area.

There are two main challenges that must be addressed in catalytic water oxidation reaction and for the efficient and economical production of hydrogen. Firstly, the catalyst used for this reaction should operate at low overpotentials. Secondly, it should be prepared from earth abundant and cheap elements. Therefore, researchers have focused on designing and preparing new catalyst systems to overcome these challenges. Nonetheless, the most promising results were achieved with catalysts consisting of rare and precious metals, namely Ru and Ir. Therefore, research on relatively cheaper and effective catalysts from earth abundant metals has increased greatly.

Metal oxide catalysts have been prepared as films or as nanomaterials with various morphologies such as spherical, rod, wire and plate and used as water oxidation electrocatalysts. Among these diverse structures, nano-sized ones are of great interest since they have the potential to be very active catalysts caused by their large surface area. Recently, bimetallic oxides with spinel or perovskite structures have

particularly drawn attention. Transition metals in such structures can have multiple oxidation states and different coordination environments. This brings the possibility to be prepared in various combinations of metals with enhanced stability and activity in catalysis applications.

The purpose of this dissertation is to develop new catalyst systems consisting of earth abundant, first row transition metal oxide nanomaterials as well as to investigate their electrocatalytic activities towards water oxidation reaction. Specifically, the following studies were performed in this dissertation;

- i) Synthesis of bimetallic oxide nanomaterials with earth abundant first row transition metals which are known to be stable and catalytically active in CuCr_2O_4 , FeMnO_3 , NiFe_2O_4 - NiO and NiCo_2O_4 - NiO structures with various morphologies such as spherical, wire and plate by facile and reproducible methods namely, sol-gel and hydrothermal routes.
- ii) Characterization of the synthesized nanomaterials by a combination of analytical techniques including XRD, SEM, TEM, EDX, XPS, ICP-OES and BET.
- iii) Preparation of electrodes by modifying conductive surfaces such as FTO and GC with synthesized nanomaterials.
- iv) Investigation of the catalytic performance of nanomaterials in electrochemical water oxidation reaction.

CHAPTER 4

EXPERIMENTAL

4.1 Materials

All reagents were used as received without further purification. Copper(II) acetate hydrate ($\text{Cu}(\text{OAc})_2 \cdot \text{H}_2\text{O}$), chromium(III) acetylacetonate ($\text{Cr}(\text{acac})_3$), manganese(II) chloride tetrahydrate ($\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$), iron(II) chloride tetrahydrate ($\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$), iron(II) nitrate hexahydrate ($\text{Fe}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$), cobalt(II) nitrate hexahydrate ($\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$), nickel(II) nitrate hexahydrate ($\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$), citric acid, nitrilotriacetic acid (NTA), urea, cetyltrimethylammonium chloride (CTAC), 2-propanol, dimethyl formamide (DMF), acetylacetone, polyethylene oxide (PEO), Triton[™] X, and Nafion[®] perfluorinated resin solution (5% wt in lower aliphatic alcohols and water) were purchased from Sigma Aldrich. Deionized water with resistivity greater than 18 M Ω (PURELAB Option-Q, ELGA) was used in the preparation of solutions throughout this study.

4.2 Synthesis of the Transition Metal Oxide Nanomaterials

4.2.1 Synthesis of CuCr_2O_4 nanoparticles

Synthesis of CuCr_2O_4 nanoparticles were carried out by using a previously reported sol-gel method with some modifications.⁵¹ Briefly, 0.005 moles of $\text{Cu}(\text{Ac})_2 \cdot \text{H}_2\text{O}$ and 0.01 moles of $\text{Cr}(\text{acac})_3$ were dissolved in 50 mL deionized water and stirred vigorously until complete dissolution. Then, 0.03 moles of citric acid was added onto the solution and stirred until a homogeneous mixture was obtained. The solution was maintained at room temperature for 30 min and then heated at 95 °C for 2 h. Obtained gel was dried in oven at 160 °C for 2 h. After drying, the citrate precursors were

calcined to eliminate the organic materials.⁵² After calcination at 600 °C for 3h, CuCr₂O₄ nanoparticles were obtained as black powder.

4.2.2 Synthesis of FeMnO₃ nanowires

Synthesis of FeMnO₃ nanowires was carried out using a previously reported solvothermal method with some modifications.⁵ Briefly, FeCl₂.4H₂O (3.0 mmol), MnCl₂.4H₂O (6.0 mmol) and NTA (4.7 mmol) were added to 30.0 mL 2-propanol and 10.0 mL deionized water mixture. After complete dissolution, the reaction mixture was transferred to a 100 mL Teflon line autoclave, which was heated to 180 °C and kept at this temperature for 6 h. The product was collected by centrifugation, and washed with deionized water and ethanol for several times. After calcination at 650 °C for 1 h, FeMnO₃ nanowires were obtained as brown powder.

4.2.3 Synthesis of NiFe₂O₄-NiO nanoparticles

NiFe₂O₄-NiO nanoparticles were synthesized by a simple hydrothermal route based on a procedure reported previously.⁵³ In brief, 2.0 mmoles of Fe(NO₃)₂.6H₂O, 4.0 mmoles of Ni(NO₃)₂.6H₂O and 12.0 mmoles of urea were dissolved in 40.0 mL of deionized water and stirred until a homogenous solution is obtained. Then, the solution was transferred a 100 mL Teflon lined autoclave and kept at 180 °C for 6 h. After the solution cooled down to room temperature, the product was separated by centrifugation and washed with deionized water and ethanol for several times. Finally, the product was dried at 90 °C followed by calcination step at 550 °C for 2 h.

4.2.4 Synthesis of NiCo₂O₄-NiO microspheres

Hierarchical NiCo₂O₄-NiO biphasic microspheres were synthesized with two different morphologies by using different structure directing agents, namely urea and CTAC.

4.2.4.1 Synthesis of urea-stabilized NiCo₂O₄-NiO microspheres

Synthesis of urea-stabilized NiCo₂O₄-NiO (U-NiCo) nanomaterials was achieved by a simple hydrothermal method reported in the literature with some modifications.⁵³ Briefly, Co(NO₃)₂.6H₂O (2.0 mmol), Ni(NO₃)₂.6H₂O (4.0 mmol) and urea (12 mmol) were dissolved in 40 mL deionized water. The obtained solution was transferred to a 100 mL Teflon-lined autoclave and kept at 180 °C for 6 h. The precipitate was separated from the mixture by centrifugation, and washed with deionized water and ethanol for several times. After drying at 90 °C, the resulting powder was calcined at 550 °C for 2 h.

4.2.4.2 Synthesis of CTAC-stabilized NiCo₂O₄-NiO microspheres

CTAC-stabilized NiCo₂O₄-NiO (C-NiCo) nanomaterials were prepared according to the hydrothermal process described above with some modifications.⁵ In brief, Co(NO₃)₂.6H₂O (3.0 mmol), Ni(NO₃)₂.6H₂O (6.0 mmol) and CTAC (4.7 mmol) were dissolved in a mixture of 2-propanol (30.0 mL) and deionized water (10.0 mL). Then, the reaction mixture was heated to 180 °C for 6 h in a 100 mL Teflon lined autoclave. The precipitate was collected by centrifugation, followed by washing with deionized water and ethanol for several times. After drying at 90 °C, the resulting powder was calcined at 550 °C for 2 h.

4.3 Materials Characterization

SEM images, EDX measurements along with elemental composition analysis were acquired by FEI Nova Nano SEM 430. TEM was carried out on JEM 2100F-RTEM and FEI Tecnai G2 F30 electron microscope operating at 300 kV. Rigaku Ultima IV X-ray diffractometer with Cu K α radiation ($\lambda = 1.54 \text{ \AA}$) was utilized to examine the phase of the nanomaterials in the 2θ range from 10° to 80° . XPS analyses were carried out on PHI-5000 VersaProbe [Physical Electronics (PHI) Chanhassen, Minneapolis, MN], equipped with Al K α at 1486.92 eV source. All data were calibrated to the hydrocarbon contamination peak at C1s of 282.4 eV. Autosorb-6 (Quantachrome Corporation) instrument was used for nitrogen adsorption-desorption experiments and BET analysis. CuCr $_2$ O $_4$ nanoparticles were dehydrated at 200 °C for 3 h, while FeMnO $_3$ nanowires, NiCo $_2$ O $_4$ -NiO microspheres and NiFe $_2$ O $_4$ -NiO nanoparticles were dehydrated at 350 °C for 3 h before analysis. Elemental composition and mass percent of each element in the structure of nanomaterials were investigated by ICP-OES with Perkin Elmer Optima 4300DV.

4.4 Electrochemical Characterization

4.4.1 Electrode preparation

In this study, GCEs (0.07 cm 2) were used in the investigation of electrochemical behaviors of CuCr $_2$ O $_4$ nanoparticles, NiCo $_2$ O $_4$ -NiO microspheres and NiFe $_2$ O $_4$ -NiO nanoparticles, while for FeMnO $_3$ nanowires, FTO coated glass electrodes (0.5 cm 2) were modified and used as working electrodes.

A modified method previously reported by Kuo et al was used in the preparation of GCEs.⁵⁴ Briefly, 11.2 mg of catalyst was dispersed in 2.0 mL of DMF by sonication. After 30 min., 19 μ L Nafion $^{\text{®}}$ solution was added and sonicated for 2 h resulting in a homogeneous ink. 5.0 μ L of the ink was dropped onto GCE and dried in an oven at 90 °C overnight. Mass loading of ca. 0.4 mg cm $^{-2}$ was obtained.

Preparation of FTO electrodes were carried out according to a previously reported method.⁵⁵ Before catalyst loading, FTO coated glass was cleaned by sonication in dilute H₂SO₄ solution for 30 min and treated at 400 °C for 30 min. Then, 100 mg of catalyst and 30 mg of PEO were dispersed in 100 μL of Triton™ X, 100 μL of acetylacetone and 1.0 mL of deionized water mixture under vigorous stirring for 24 h. 5.5 μL of the ink was transferred onto FTO glass to obtain a catalyst loading of ca. 0.92 mg cm⁻².

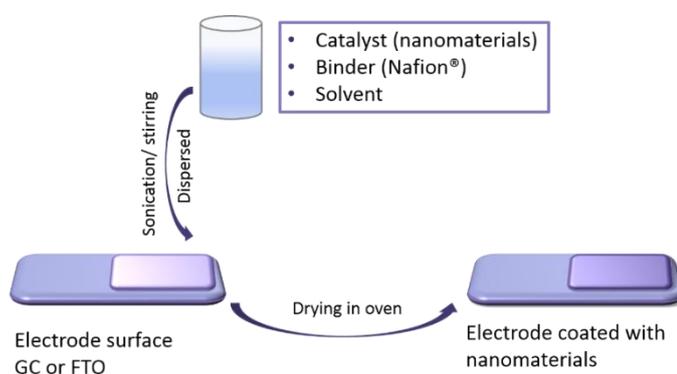

Figure 4.1. Schematic representation of modified electrode preparation

4.4.2 Electrochemical measurements

Electrochemical studies were conducted by using a Gamry 1010B potentiostat-galvanostat and a standard three-electrode system (Figure 4.2). In this system, Pt wire and Ag/AgCl (in 3.0 M KCl) were used as counter electrode (CE) and reference electrode (RE), respectively. GCEs coated with CuCr₂O₄ nanoparticles, NiCo₂O₄-NiO microspheres and NiFe₂O₄-NiO nanoparticles and FTO modified with FeMnO₃ nanowires were used as working electrodes (WE).

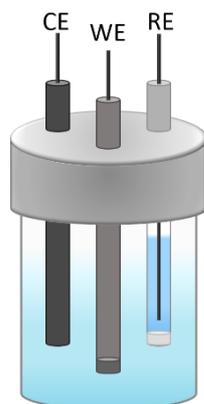

Figure 4.2. Schematic representation of a standard three-electrode system used for the electrochemical studies of electrodes modified with nanomaterials

Electrochemical behavior of the modified electrodes was investigated in 0.1 M KOH solution at room temperature. Polarization curves were recorded at a scan rate of 5 mV s^{-1} . All potentials, measured in this work were corrected for iR drop, and reported against reversible hydrogen electrode (RHE). The conversion of the obtained potential (vs Ag/AgCl) was carried out according to Nernst equation (4.1) and overpotential, η was calculated using equation (4.2).

$$E_{\text{RHE}} = E_{\text{Ag/AgCl}} + 0.059 \text{ pH} + E^{\circ}_{\text{Ag/AgCl}} \quad (4.1)$$

$$\eta = E_{\text{RHE}} - 1.23 \text{ V} \quad (4.2)$$

The water oxidation kinetics of the nanomaterials were elucidated by fitting the linear part of polarization curves to Tafel equation (equation (3.5)) where η is the overpotential, a , j and b are intercept to find exchange current density (j_0), current density and Tafel slope, respectively.

The stability of the modified electrodes was investigated via constant potential electrolysis at certain overpotentials which correspond to current densities of 5 mA cm^{-2} in 0.1 M KOH. Electrochemical impedance spectroscopy (EIS) analyses were carried out at various potentials in the frequency range of 0.1 Hz – 100 kHz and with an amplitude of 10 mV.

Electrochemically active surface area (ECSA) of the catalysts were estimated by determining the electrochemical double-layer capacitance (C_{dl}). The values of C_{dl} were determined by recording cyclic voltammograms (CVs) at non-Faradaic potential window (1.177-1.277 V vs RHE) and at various scan rates (5-10-15-20-25 mV s^{-1}). The plot of double-layer charging current (at 1.27 V vs RHE) versus scan rate resulted in a straight line whose slope yield C_{dl} values of the catalysts. The ECSA values were then determined by using equation (3.7). C_s is the specific capacitance of the sample where $C_s = 0.06 \text{ mF cm}^{-2}$ for smooth metal oxide surfaces.^{56,57}

Surface roughness factor (RF) was calculated by dividing ECSA of the catalyst to the geometric surface area (GSA) of the electrode (equation (3.8)).

Mass activity (A g^{-1}) values were determined according to equation (4.3) by using the catalyst loading, m (mg cm^{-2}) and current density, j (mA cm^{-2}) at a certain overpotential.

$$\text{Mass activity} = \frac{j}{m} \quad (4.3)$$

Specific activity ($\text{mA cm}^{-2}_{\text{ECSA}}$) was calculated by using equation (4.4) where i is the observed current at a certain potential.²⁹

$$\text{Specific activity} = \frac{i}{\text{ECSA}} \quad (4.4)$$

Water oxidation activity of FTO modified with FeMnO_3 nanowires were tested by measuring the volume of O_2 gas evolved during electrolysis at a constant current of 5 mA for 1 h using a Hoffmann electrolysis apparatus (Figure 4.3). Faradaic yield, which is described as the ratio of the amount of O_2 gas generated experimentally to the theoretical amount, was calculated. Theoretical amount of O_2 was determined by using the following relations:

- i.* By using Faraday's relation (equation (4.5)) amount of charges (Q) passing through the system was calculated, where i is the current (A) and t is time (s).

$$Q = i \cdot t \quad (4.5)$$

- ii. Mole of O₂ (n(O₂)) was calculated by equation (4.6) where n_{e⁻} is the mole of electrons passing the system for O₂ generation (4 moles) and F is the Faraday's constant (96485 C mol⁻¹).

$$n(\text{O}_2) = \frac{Q}{n_{e^-} \times F} \quad (4.6)$$

- iii. Theoretical volume of O₂ (V(O₂)) was calculated using ideal gas law (equation 4.7) where P is atmospheric pressure which is 0.9 atm in Ankara, T is temperature (K) and R is the ideal gas constant (0.082 L atm mol⁻¹ K⁻¹).

$$P V(\text{O}_2) = n(\text{O}_2)RT \quad (4.7)$$

CHAPTER 5

RESULTS AND DISCUSSION

5.1 Characterization of Transition Metal Oxide Nanomaterials

5.1.1 Characterization of CuCr_2O_4 Nanoparticles

CuCr_2O_4 nanoparticles were synthesized by modified sol-gel method. The formation of nanoparticles took place in aqueous medium where citric acid function as chelating agent (Figure 5.1). TEM images of the as-synthesized CuCr_2O_4 nanoparticles are displayed in Figure 5.2a-c. The images show that CuCr_2O_4 particles have quasi-spherical morphology with average size of $28 \text{ nm} \pm 6 \text{ nm}$. The particle size distribution histogram is given in Figure 5.2d. The spacing between lattice fringes is measured as 3.5 \AA , which is in agreement with the d-spacing of (220) plane of CuCr_2O_4 .⁵⁸ EDX analysis performed in conjunction with SEM verifies the presence of Cu and Cr in the nanoparticles (Figure 5.3).

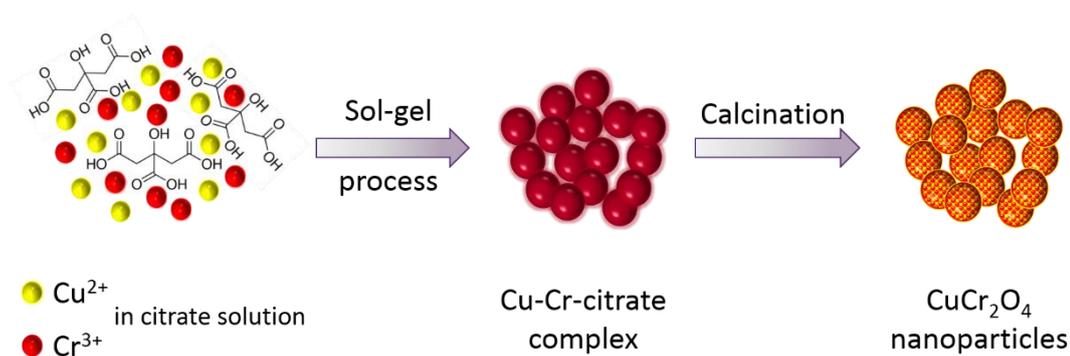

Figure 5.1. Illustration for the formation of CuCr_2O_4 nanoparticles

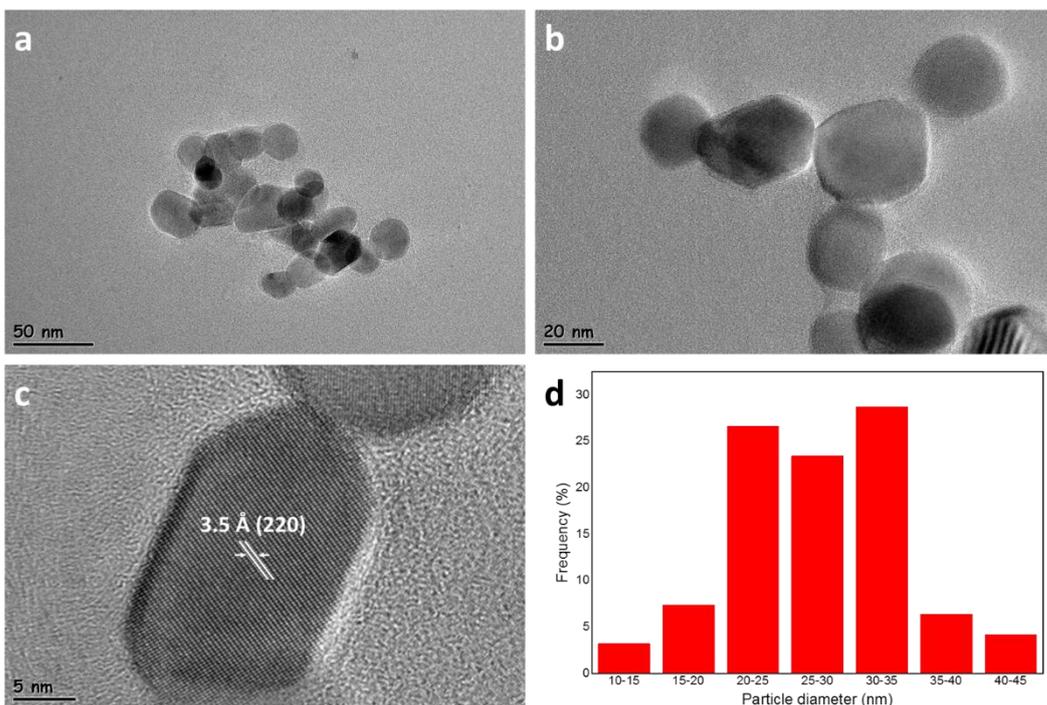

Figure 5.2. (a-c) TEM images and (d) particle size distribution graph of CuCr_2O_4 nanoparticles

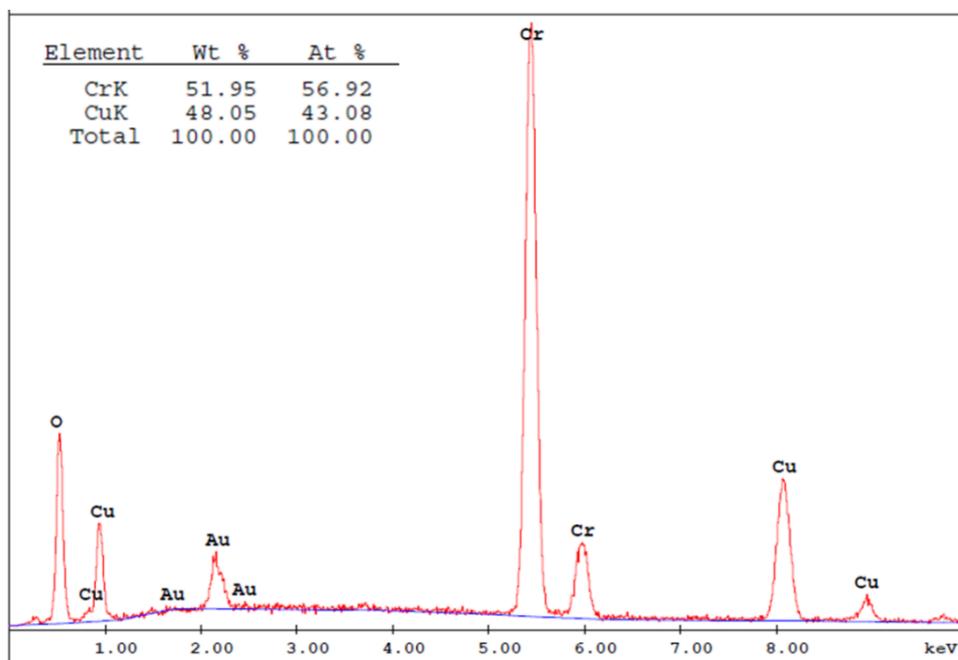

Figure 5.3. EDX spectrum of CuCr_2O_4 nanoparticles

The XRD pattern of CuCr_2O_4 nanoparticles is shown in Figure 5.4. The peaks with 2θ values of 31.23° , 35.36° , 37.83° , 56.37° and 64.94° correspond to the (112), (211), (202), (321) and (411) planes of cubic CuCr_2O_4 , respectively (JCPDS 34-0424). Lack of secondary phase diffractions due to the impurities of oxides of Cu and Cr indicates that obtained nanoparticles are purely spinel CuCr_2O_4 . The sizes of the crystallites are estimated with XRD peak analysis as ca. 35 nm. The analysis was done for the diffraction peak at 35.36° ((211) plane) by using Debye-Scherrer equation (equation 2.1).³⁸ This value is consistent with the results obtained by TEM analysis.

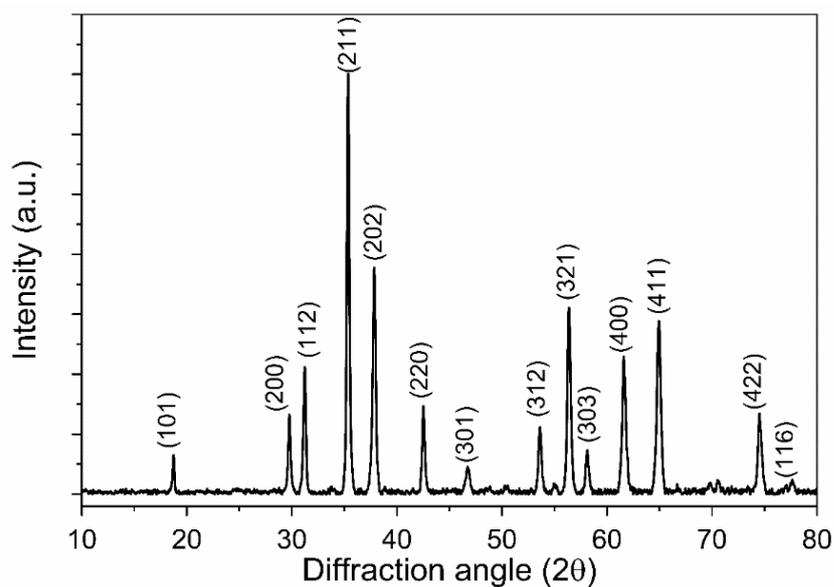

Figure 5.4. XRD pattern of CuCr_2O_4 nanoparticles (JCPDS 34-0424)

The O 1s, Cu 2p, Cr 2p along with survey XPS spectra of CuCr_2O_4 nanoparticles are demonstrated in Figure 5.5 and 5.6. The survey spectrum suggests the presence of only Cu, Cr and O. No species contaminating the synthesized nanoparticles are observed, except low amount of carbon (C1s at 282.3 eV) used for calibration (Figure 5.5). Cu 2p core level spectrum shows two characteristic peaks corresponding to Cu $2p_{3/2}$ at binding energies of 932.0 eV and 929.4 eV (Figure

5.6a). The strong satellite features, which are on the high-binding energy side, indicate the presence of copper in oxidation state of +2. The low-energy Cu 2p_{3/2} peak at 929.4 eV is attributed to Cu²⁺ in octahedral voids while the high-energy Cu 2p_{3/2} at 932.0 eV is assigned as Cu²⁺ in tetrahedral voids. The observed Cu 2p_{3/2} peaks verify the presence of CuCr₂O₄ spinel structure.⁵⁸⁻⁶⁰ Figure 5.6b shows Cr 2p core level spectrum. The two peaks corresponding to 2p_{1/2} and 2p_{3/2} are observed at 583.2 eV and 573.3 eV, respectively. Further resolution of these peaks reveal two Gaussian bands which are ascribed to Cr³⁺ (582.9 eV and 573.0 eV) and Cr⁶⁺ (584.4 eV and 574.1 eV).^{61,62} Presence of Cr⁶⁺ in CuCr₂O₄ structure is unexpected. The possible reason for observing this ion may be due to the oxidation of Cr³⁺ species on the nanoparticles' surface.⁶¹ The O 1s spectrum given in Figure 5.6c demonstrates a peak around 527.3 eV, which is further resolved to three Gaussian bands. The one observed at 527.2 eV (I) is attributed to metal-oxygen bonds, while the ones at 528.1 eV (II) and 529.1 eV (III) are assigned to defect sites with low oxygen coordination and surface adsorbed oxygen species (O₂²⁻, OH⁻) on the materials' surface, respectively.^{23,29,63,64}

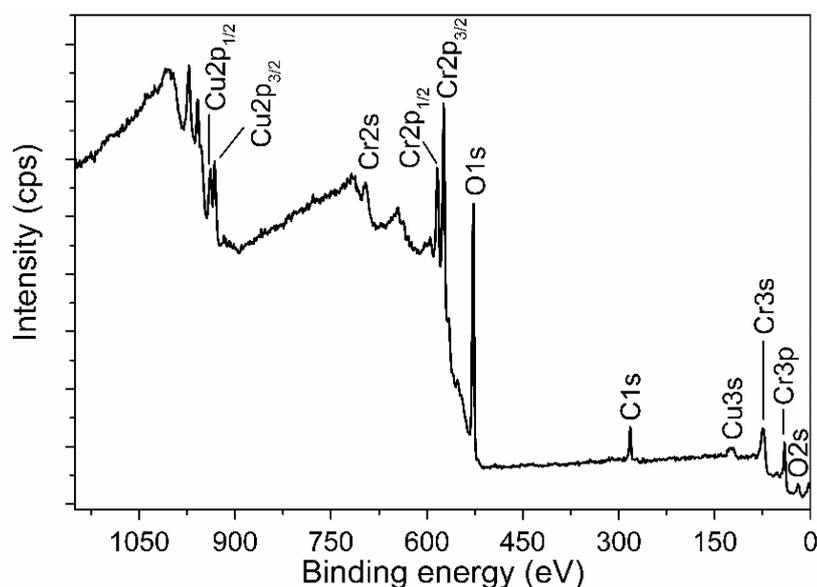

Figure 5.5. XPS survey spectrum of CuCr₂O₄ nanoparticles

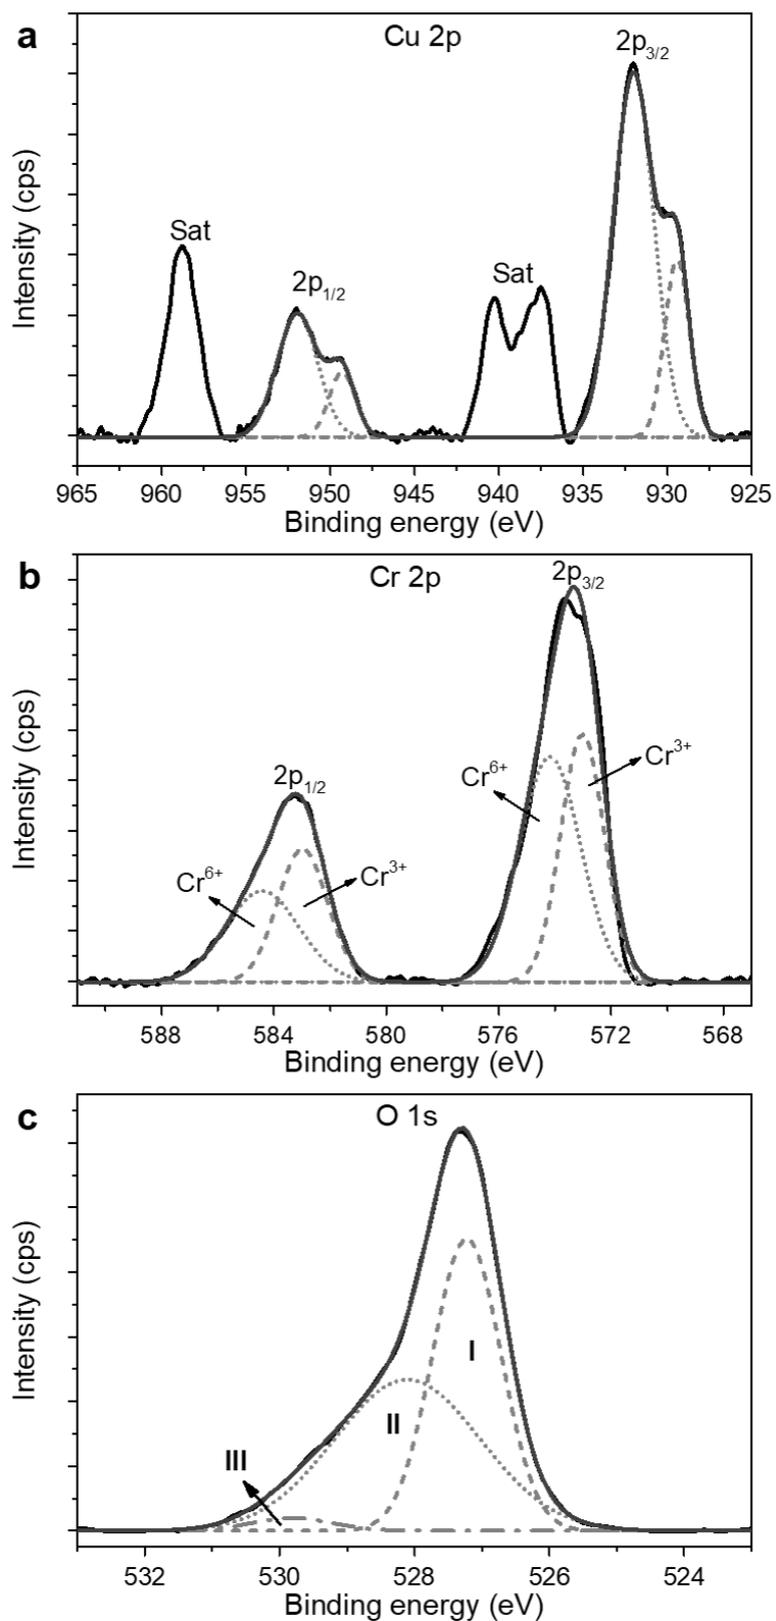

Figure 5.6. XPS (a) Cu 2p, (b) Cr 2p and (c) O 1s spectra of CuCr₂O₄ nanoparticles

Elemental composition and mass percent of each element present in the nanomaterials were investigated by ICP-OES. The amount of Cu and Cr in CuCr_2O_4 nanoparticles as wt% were determined as 24.6 ± 0.5 and 38.8 ± 0.3 , while theoretically they were calculated as 27.4 % and 44.9 %, respectively. The most likely reason for the observed difference in the amount of Cu and Cr is the solubility problem of the sample encountered during analysis. Even though a percent error of 10.3 % and 13.6 % were obtained for Cu and Cr, respectively, relative molar ratio of the elements are consistent with the expected 1:2 (Cu:Cr) ratio.

N_2 adsorption-desorption analysis was performed in order to examine BET surface area and pore size of the synthesized nanoparticles. CuCr_2O_4 nanoparticles exhibit BET surface area of $10.63 \text{ m}^2 \text{ g}^{-1}$. The observed isotherm (Figure A.1) indicate the mesoporous nature of CuCr_2O_4 nanoparticles. Moreover, large surface area and porosity are also important parameters in catalysis since they promote the interaction between catalyst and reactants/reaction intermediates, and thus enhance catalyst activity.

5.1.2 Characterization of FeMnO_3 nanowires

The synthesis of FeMnO_3 nanowires was performed with a simple modified hydrothermal method. Formation of the nanowires took place in isopropyl alcohol and deionized water mixture where NTA function as structure directing agent. As illustrated in Figure 5.7, after dissolution of metal salts, the transition metal ions react with NTA to form FeMn-NTA complex during hydrothermal reaction. Then, through calcination FeMnO_3 nanowires are synthesized.

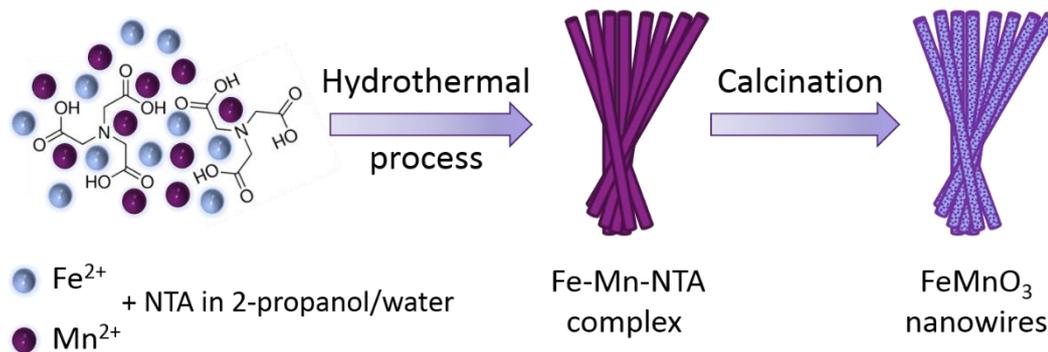

Figure 5.7. Illustration for the formation of FeMnO₃ nanowires

Figure 5.8 shows SEM and TEM images of FeMnO₃ nanowires. The images reveal that about 70 nm size nanoparticles assemble to form the wires. The images also demonstrate that the nanowires have several micrometers of length and approximately 200 nm of thickness. EDX analysis verifies the presence of Fe and Mn in the synthesized nanowires (Figure 5.9). The composition of the FeMnO₃ nanowires was studied by the elemental mapping of Fe, Mn and O elements on the nanowires (Figure 5.8g). The mapping reveal that the elements forming the nanowires are uniformly distributed across the whole material.

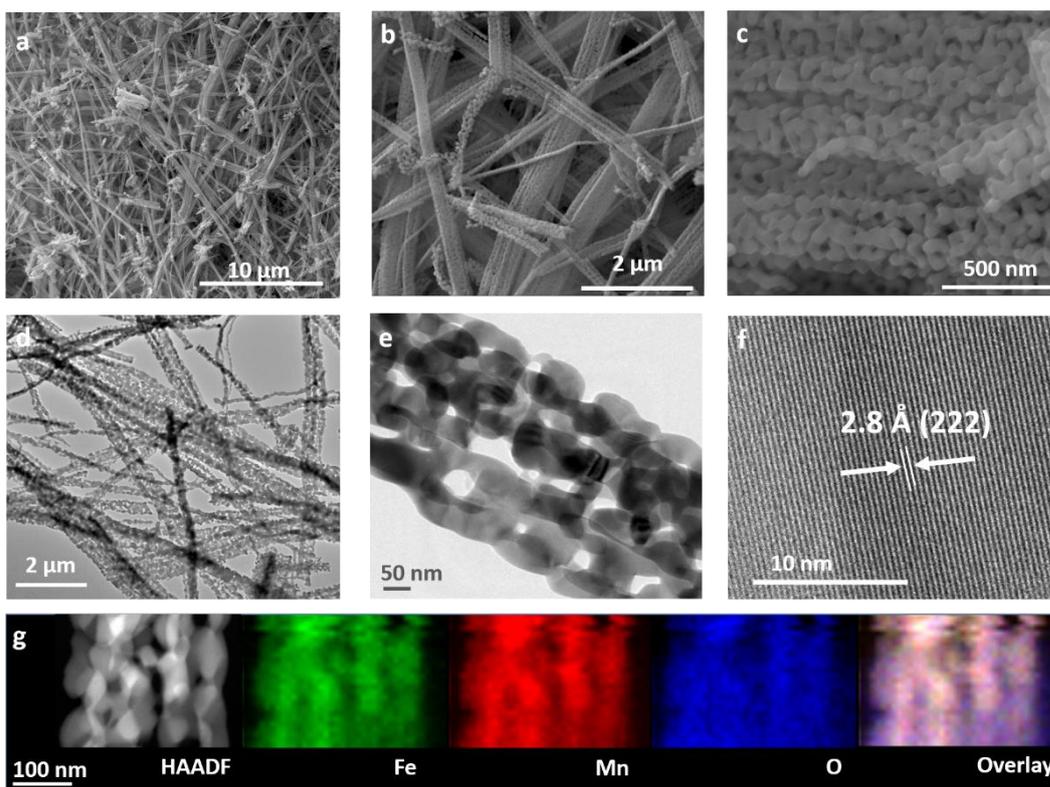

Figure 5.8. (a-c) SEM images and (d-f) TEM images at different magnifications, (g) HAADF-STEM image and element mapping (Fe (green), Mn (red) and O (blue)) of FeMnO₃ nanowires

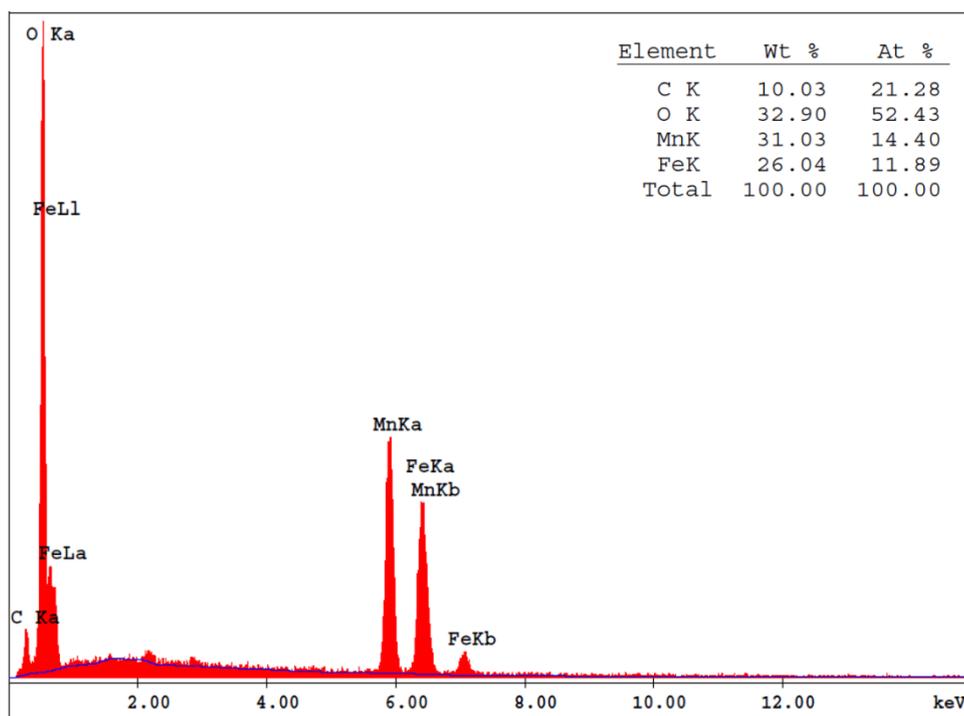

Figure 5.9. EDX spectrum of FeMnO₃ nanowires

The XRD pattern of nanowires is shown in Figure 5.10. The peaks with 2θ values of 23.16° , 32.96° , 35.65° , 38.24° , 40.65° , 42.98° , 45.18° , 47.23° , 49.34° , 53.28° , 55.16° , 57.06° , 58.82° , 60.58° , 62.37° , 64.06° , 65.76° , 67.42° , 69.08° , 70.72° , 72.33° , 74.00° and 75.54° were indexed to the (211), (222), (320), (400), (411), (420), (332), (422), (134), (125), (440), (433), (600), (611), (026), (145), (622), (136), (444), (543), (046), (721) and (642) planes of FeMnO₃ bixbyite structure (PDF number 01-076-0076), respectively. No diffraction peaks other than those of FeMnO₃ were observed in the XRD pattern. XRD peak analysis was performed for the diffraction peak at 32.96° (222), using the Debye-Scherrer equation to estimate crystallite size.³⁸ The analysis revealed that sizes of the crystallites are ca. 46.8 nm for FeMnO₃ nanowires. The crystallite sizes are slightly smaller than particle sizes measured by TEM analysis.

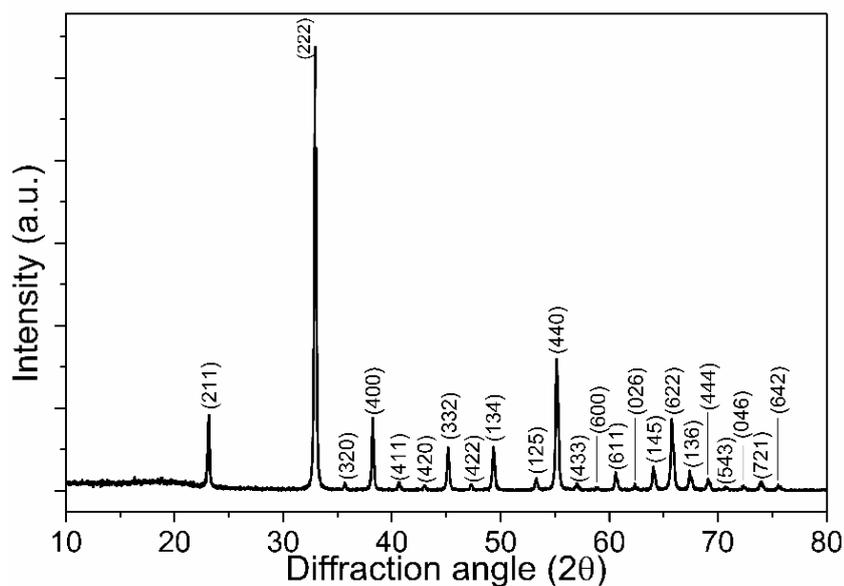

Figure 5.10. XRD pattern of FeMnO₃ nanowires (PDF number 01-076-0076)

The XPS spectra of FeMnO₃ nanowires are demonstrated in Figures 5.11 and 5.12. The survey spectrum of nanowires suggests the presence of only Mn, Fe and O elements (Figure 5.11). Only contamination observed in the sample was low quantity of carbon (C1s at 282.4 eV) which is used for calibration. Fe 2p core-level spectrum demonstrates two peaks at binding energies of 708.4 eV and 722.1 eV corresponding to Fe 2p_{3/2} and Fe 2p_{1/2} peaks, respectively (Figure 5.12a). The Gaussian fit unveiled two bands under Fe 2p peaks, which are ascribed to Fe²⁺ (708.0 eV and 721.9 eV) and Fe³⁺ (709.7 eV and 724.3 eV). The observed peaks and their positions agree well with the ones reported previously.^{61,65-67} Mn 2p core-level spectrum is demonstrated in Figure 5.12b. The spectrum shows two major peaks at 638.9 eV and 650.8 eV, which are assigned as Mn 2p_{3/2} and Mn 2p_{1/2}, respectively. Mn 2p peaks were resolved further and fitted bands of Mn³⁺ (638.8 eV and 650.5 eV) and Mn⁴⁺ (640.0 eV and 651.6 eV).^{61,65,68} The O 1s spectrum exhibits a peak at 527.3 eV (Figure 5.12c). The curve-fitting process revealed two Gaussian (I and II) bands. The one at 527.2 eV (I) corresponds to metal-oxygen bonding in the sample while the one at

528.4 eV (II) is assigned to surface adsorbed oxygen species (i.e. O_2^{2-} , OH^-) suggesting the presence of low oxygen coordination sites in the nanowires.^{65,66,68-70}

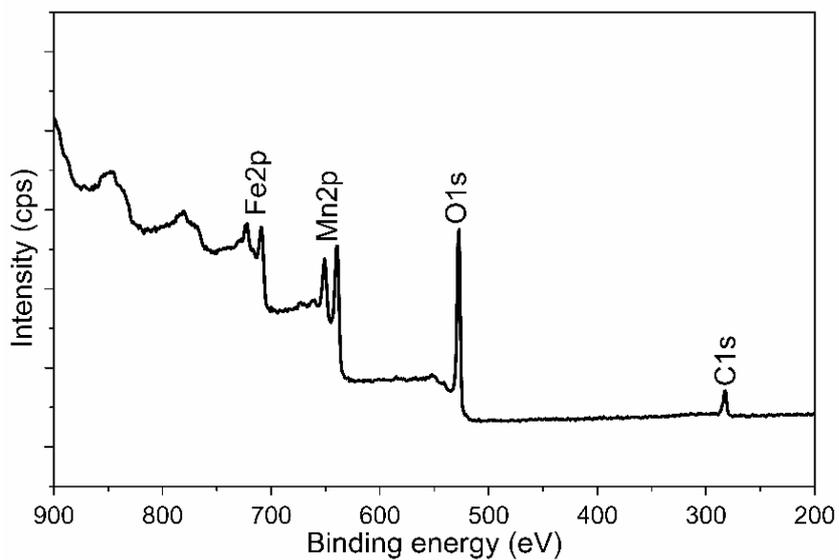

Figure 5.11. XPS survey spectrum of $FeMnO_3$ nanowires

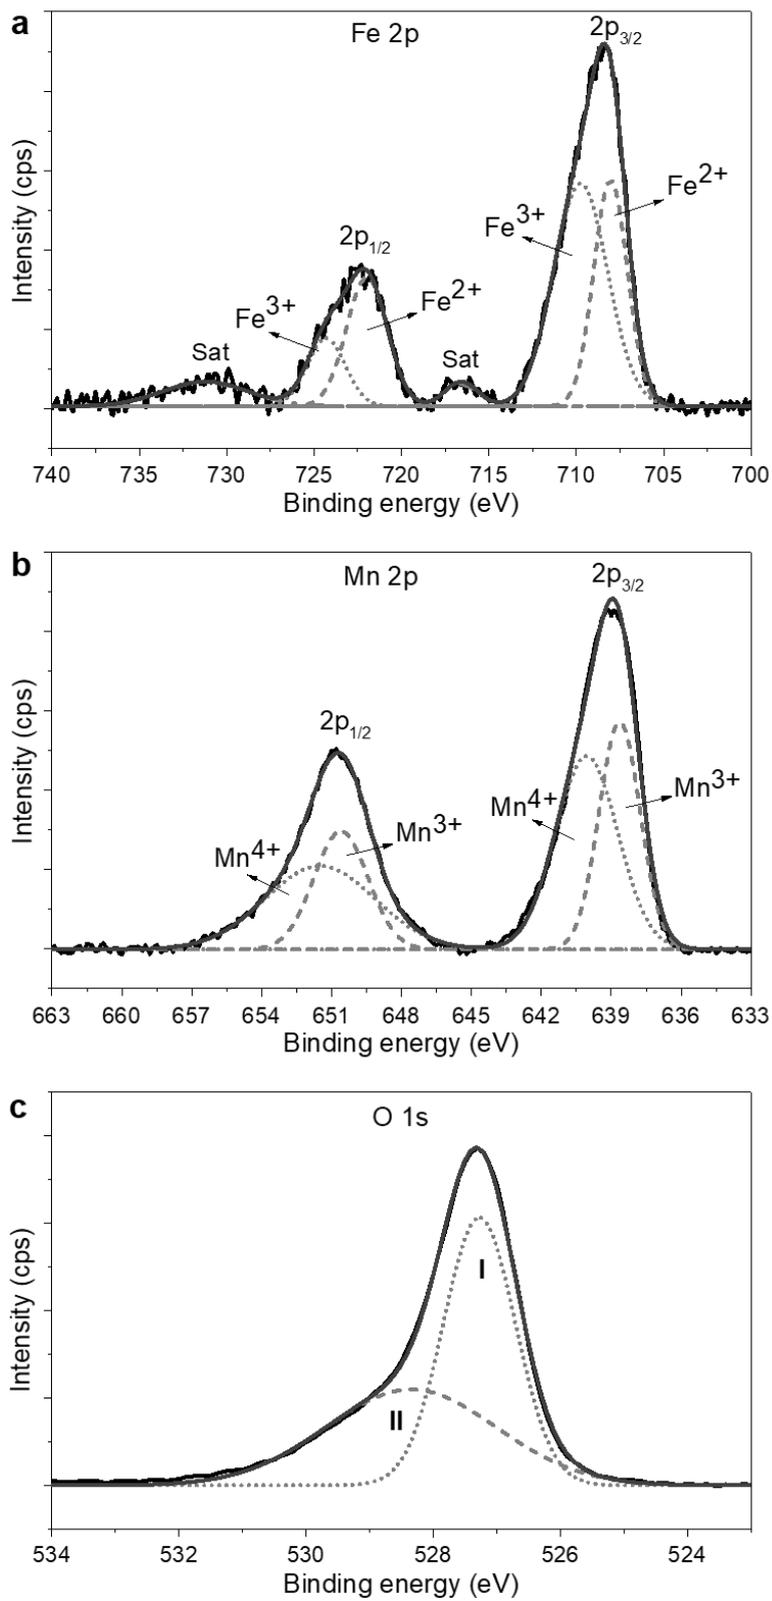

Figure 5.12. XPS (a) Fe 2p, (b) Mn 2p and (c) O 1s spectra of FeMnO₃ nanowires

Elemental composition and mass percent of each element in the nanowires were investigated by ICP-OES, and the amount of Mn and Fe found to be 36.6 wt% and 29.2 wt%, respectively. However, theoretical values for Mn wt% and Fe wt% were determined to be 34.6 % and 35.2 %, respectively. Similar to the ones of CuCr_2O_4 nanoparticles, for this material too ICP-OES analysis resulted in a 17.0 % error, which can also be due to solubility problem of the synthesized material. The BET surface area was measured as $14.21 \text{ m}^2 \text{ g}^{-1}$ for FeMnO_3 nanowires. FeMnO_3 nanowires were observed to have higher surface area than the one of CuCr_2O_4 nanoparticles. Large surface area is very important for not only catalysis but also for many other potential applications. Therefore, larger surface area of FeMnO_3 nanowires suggest them to be more advantageous for the desired applications compared to CuCr_2O_4 .

5.1.3 Characterization of NiFe_2O_4 -NiO Nanoparticles

NiFe_2O_4 -NiO nanoparticles were synthesized via simple hydrothermal method where urea was used as surfactant. The urea molecules could react with Ni^{2+} and Fe^{2+} ions and form Ni-Fe-urea precursor complex, which was later calcined in air to obtain NiFe_2O_4 -NiO nanoparticles (Figure 5.13).

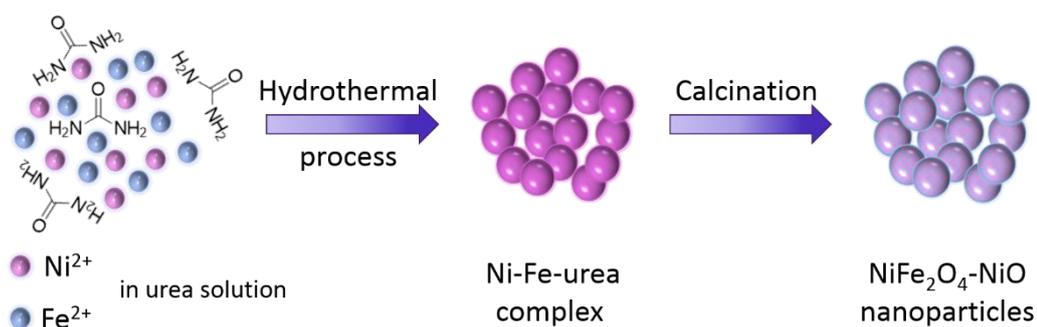

Figure 5.13. Illustration for the formation of NiFe_2O_4 -NiO nanoparticles

SEM and TEM images of the materials are given in Figure 5.14. The microscopy images show that $\text{NiFe}_2\text{O}_4\text{-NiO}$ nanomaterial is composed of spherical-like particles with average size of 35 nm. EDX spectrum of the particles confirms the presence of Ni and Fe in the materials' structure (Figure 5.15). The detailed analysis on the composition of the nanoparticles with elemental mapping shows that Ni, Fe and O elements are homogeneously distributed across the whole structure (Figure 5.14g).

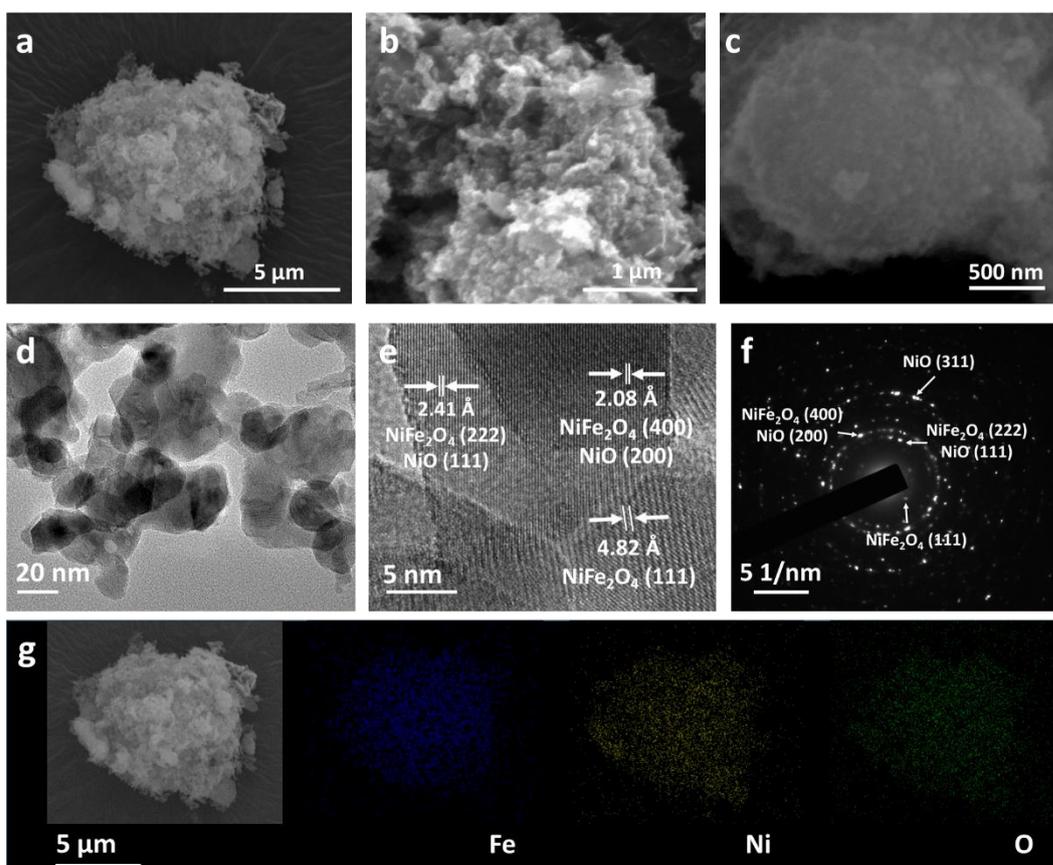

Figure 5.14. (a-c) SEM and (d-e) TEM images at different magnifications, (f) SAED pattern and (g) element mapping (Fe (blue), (Ni (yellow), O (green) of $\text{NiFe}_2\text{O}_4\text{-NiO}$ nanoparticles

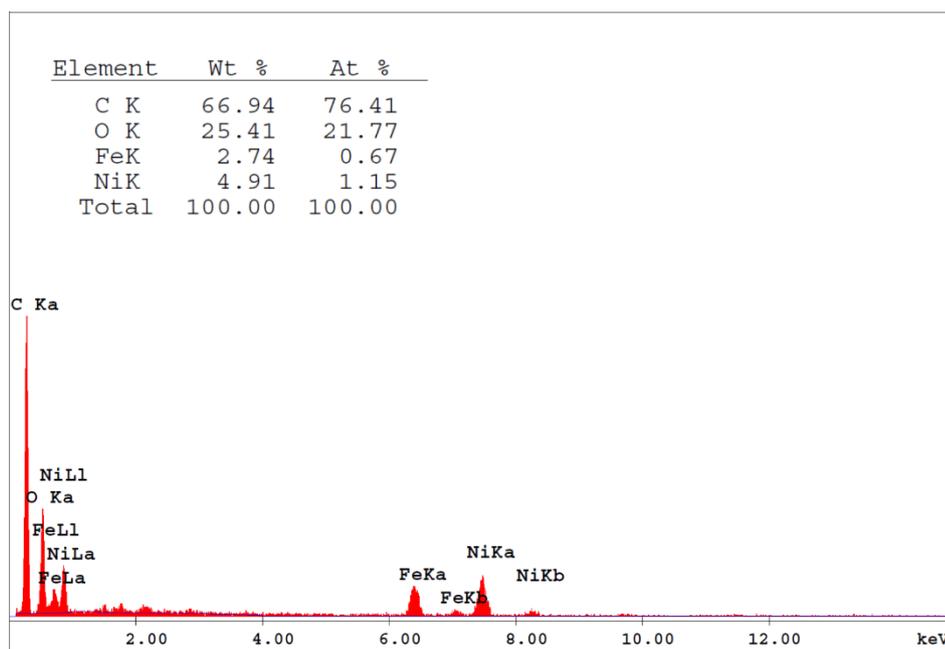

Figure 5.15. EDX spectrum of NiFe₂O₄-NiO nanoparticles

Figure 5.16 shows the XRD pattern of NiFe₂O₄-NiO nanoparticles. The peaks located at 2θ values of 18.4°, 30.4°, 35.7°, 37.3°, 43.4°, 54.0°, 57.5°, 63.1°, 71.6° and 74.7° are attributed to (111), (220), (311), (222), (400), (422), (511), (440), (620) and (533) planes of NiFe₂O₄ (PDF 00-003-0875), respectively. In addition, peaks corresponding to (111), (200), (220) and (311) planes of cubic NiO (PDF 01-071-1179) are observed at 2θ values of 37.3°, 43.4°, 63.1° and 75.5°, indicating the co-formation of NiO and NiFe₂O₄. (222), (400) and (440) diffraction peaks of NiFe₂O₄ coincide with (111), (200) and (220) peaks of NiO, respectively. The reason for this observation is mainly because the unit cell parameters of NiFe₂O₄ and NiO are very similar.⁷¹⁻⁷⁴ The crystallite size was calculated as ca. 15.1 nm based on the diffraction peak at 43.4°. The crystallite size is slightly smaller than particle size measured by TEM analysis.

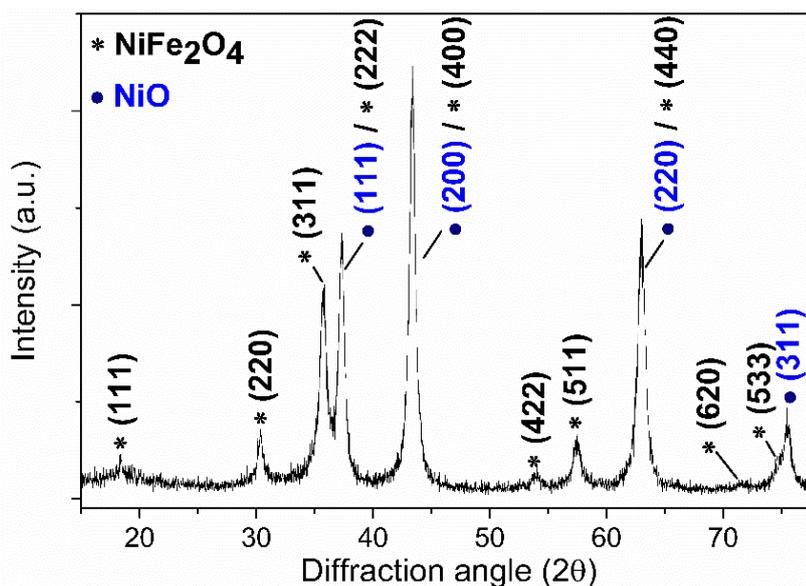

Figure 5.16. XRD pattern of NiFe₂O₄-NiO nanoparticles

XPS survey spectrum along with Ni 2p, Fe 2p and O 1s spectra of NiFe₂O₄-NiO nanomaterials are given in Figures 5.17 and 5.18. Survey spectrum affirms the presence of only Ni, Fe and O in the nanomaterial (Figure 5.17) in addition to C, which was used for calibration. Ni 2p core level spectrum is shown in Figure 5.18a. Two characteristic peaks at 855.6 eV and 873.4 eV corresponding to Ni 2p_{3/2} and Ni 2p_{1/2} were observed together with two shakeup satellite peaks, which suggest the presence of Ni²⁺ in the materials.^{71,75} Deconvolution of these peaks resulted in two Gaussians indicative of co-existence of Ni²⁺ (855.4 eV and 873.2 eV) and Ni³⁺ (857.3 eV and 875.1 eV) ions in NiFe₂O₄-NiO.^{30,76} Fe 2p core level spectrum displays two spin-orbit doublets, 2p_{3/2} and 2p_{1/2}, at 711.6 eV and 724.6 eV, respectively (Figure 5.18b). Absence of satellite peaks confirms that Fe₃O₄ or Fe₂O₃ is not formed and NiFe₂O₄-NiO structure comprise of Fe³⁺ ions.^{30,77-79} Fitting of O 1s core level spectrum revealed three oxygen contributions which are attributed to metal-oxygen bond (529.9 eV, peak I), oxygen deficient sites and oxygen species (O₂²⁻, OH⁻) adsorbed onto the nanomaterials' surface (531.1 eV, peak II and 534.2 eV, peak III) (Figure 5.18c).⁸⁰

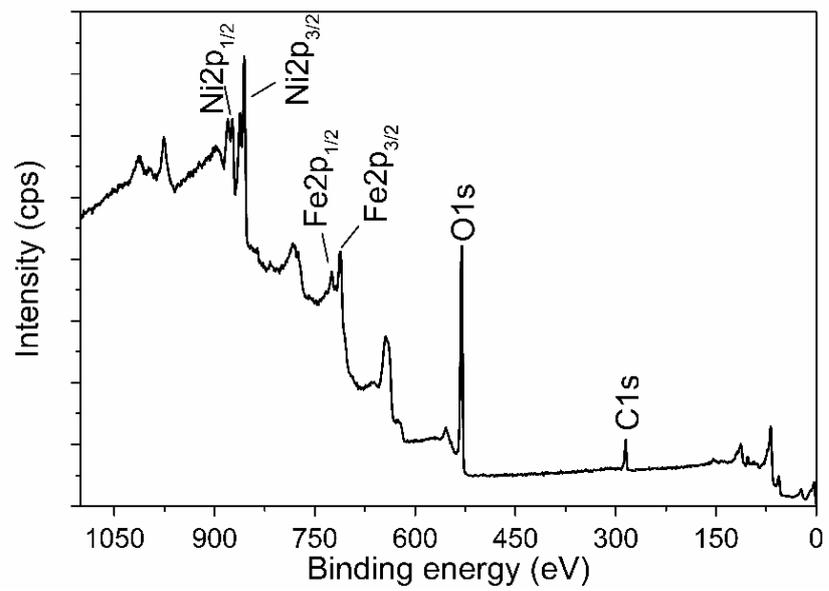

Figure 5.17. XPS survey spectrum of NiFe₂O₄-NiO nanoparticles

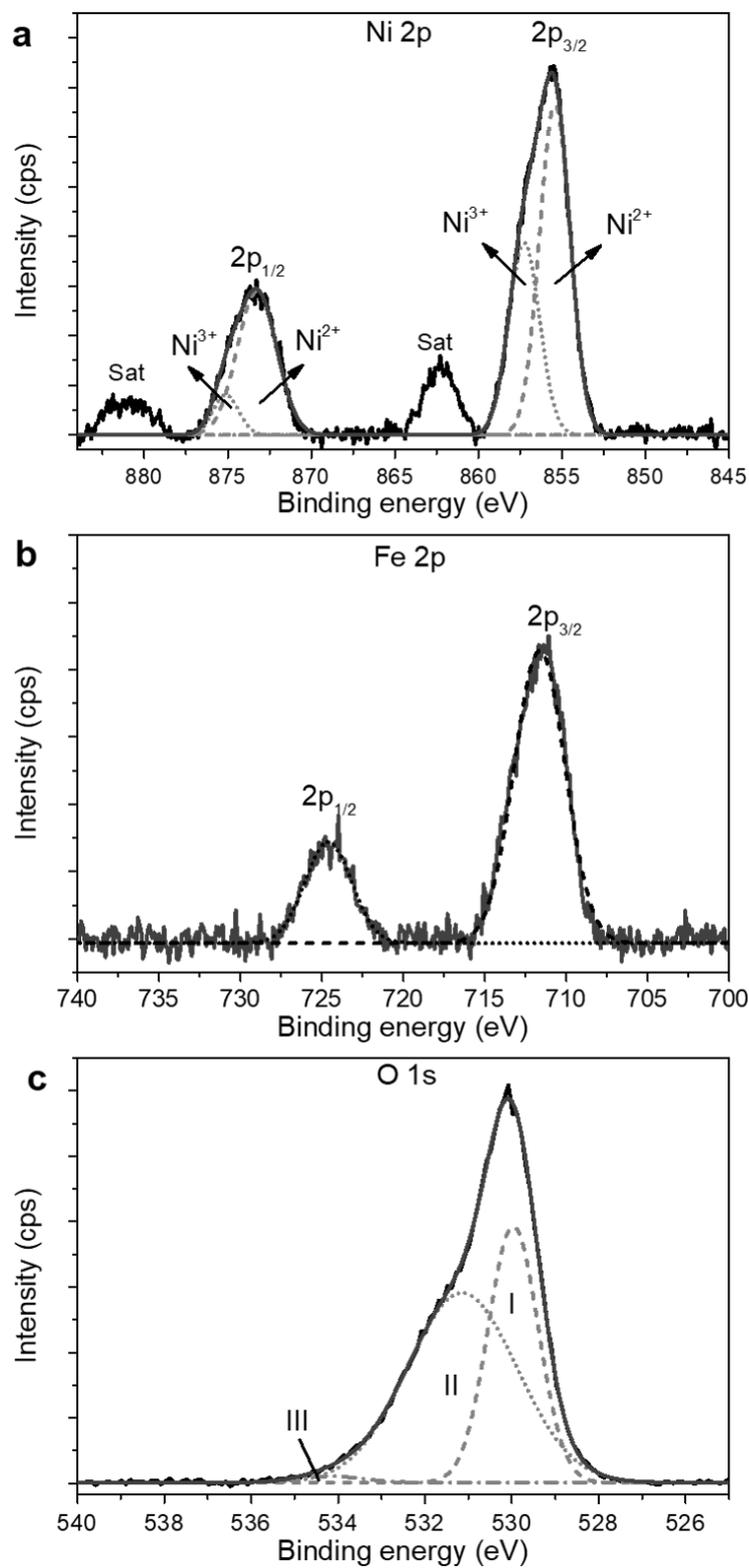

Figure 5.18. XPS (a) Ni 2p, (b) Fe2p and (c) O 1s spectra NiFe₂O₄-NiO nanoparticles

ICP-OES was utilized to investigate the elemental composition and mass percent of each element in the material, and the amount of Fe and Ni were determined to be 21 wt% and 49 wt%, respectively. The mole ratio was calculated using ICP-OES data. The calculation resulted in NiFe₂O₄:NiO ratio of 1:3.44 which suggest presence of higher amount of NiO in the synthesized material. BET surface area and pore size of nanomaterials were studied via N₂ adsorption-desorption analysis. The isotherm can be categorized as type IV based on the International Union of Pure and Applied Chemistry (IUPAC) classification.^{81,82} NiFe₂O₄-NiO nanoparticles exhibit a large BET surface area of 79.04 m² g⁻¹ along with pore size and pore volume of 4.4 nm and 0.62 cm³ g⁻¹, respectively. Pore size data along with BET isotherm (Figure A2) show that obtained NiFe₂O₄-NiO nanoparticles have mesoporous nature. Large surface area and high porosity of this material are believed to have significant effect on water oxidation activity.

5.1.4 Characterization of NiCo₂O₄-NiO Microspheres

NiCo₂O₄-NiO nanomaterials were synthesized in two different morphologies via two different structure directing agents; urea and CTAC through simple hydrothermal method. Similar to that of FeMnO₃ nanowires and NiFe₂O₄-NiO nanoparticles, in NiCo₂O₄-NiO nanomaterials too, CTAC and urea coordinate to transition metal ions and gather to form microspheres of NiCo-surfactant precursor complexes. The formation of NiCo₂O₄-NiO structures take place by the following calcination step. Reaction with urea resulted in urchin-like morphology (Figure 5.19) while with use of CTAC microspheres with nanoplate assembly are formed (Figure 5.20).

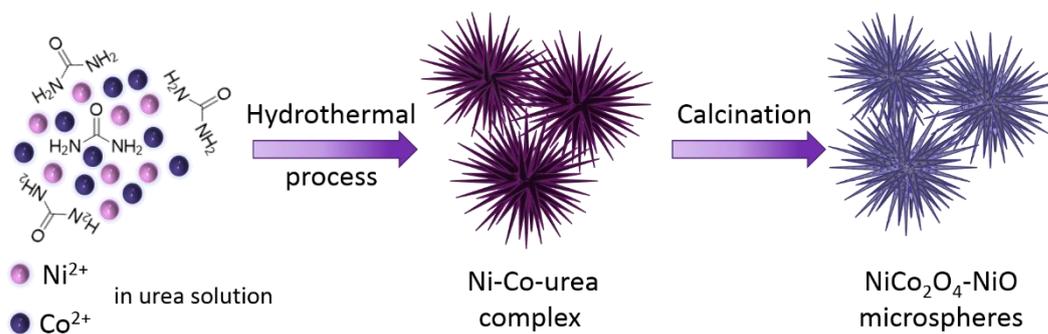

Figure 5.19. Illustration for the formation of urea stabilized NiCo_2O_4 -NiO microspheres

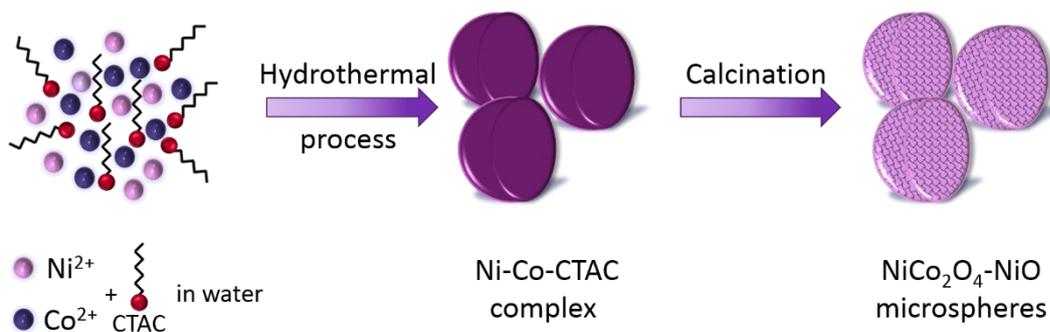

Figure 5.20. Illustration for the formation of CTAC stabilized NiCo_2O_4 -NiO microspheres

Figure 5.21 displays the SEM and TEM images of hierarchical NiCo_2O_4 -NiO nanomaterials synthesized by using urea (U-NiCo). The microscopy images exhibit that urchin-like microspheres are formed by the assembly of NWs grown out from the center of the spheres. The NWs have approximately $650 \text{ nm} \pm 50 \text{ nm}$ of length and $75 \text{ nm} \pm 10 \text{ nm}$ of thickness. Further inspection of the images reveals that Nanoparticles with average size of $25 \text{ nm} \pm 5 \text{ nm}$ are assembled to form the observed NWs. EDX analysis which was performed in conjunction with SEM analysis confirm the existence of Co and Ni in the synthesized hierarchical nanomaterial (Figure 5.22).

A detailed analysis on the elemental composition of the material was studied by elemental mapping of Ni, Co and O on the urchin-like microspheres. The mapping shows the uniform distribution of the elements forming the nanomaterial (Figure 5.21g).

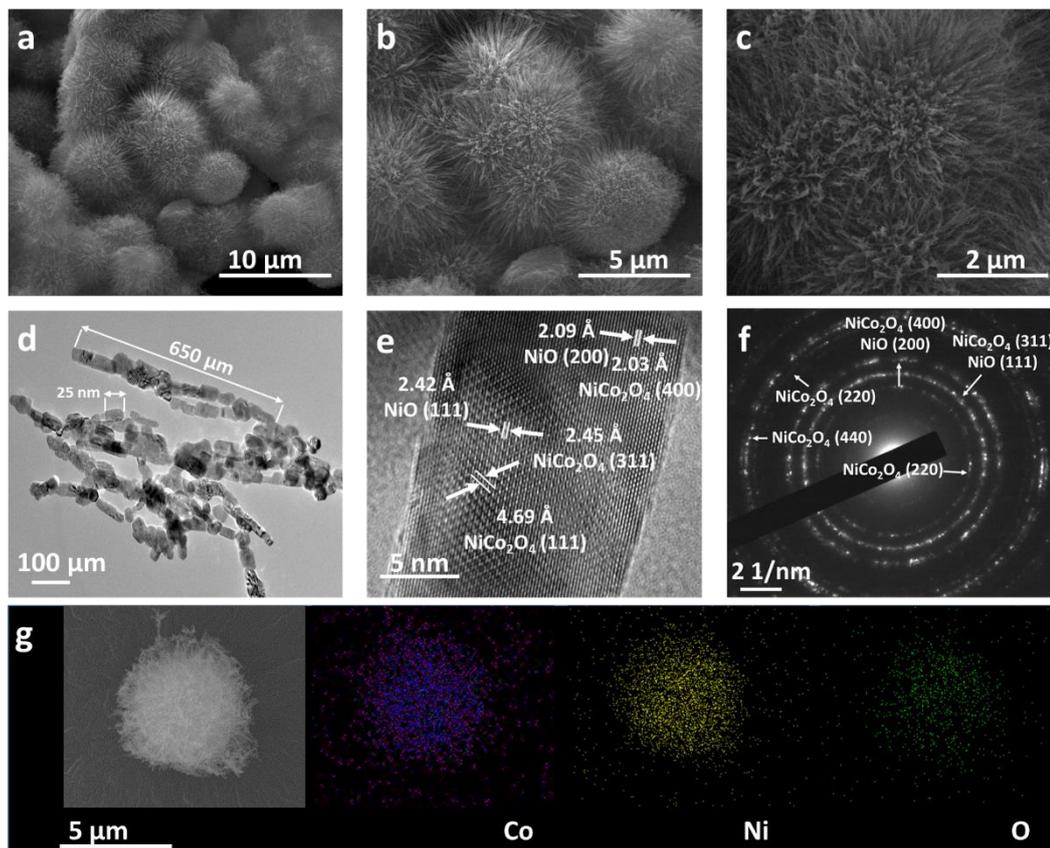

Figure 5.21. (a-c) SEM and (d-e) TEM images at different magnification, (f) SAED pattern and (g) Element mapping (Co (blue), Ni (yellow), O (green)) of U-NiCo microspheres

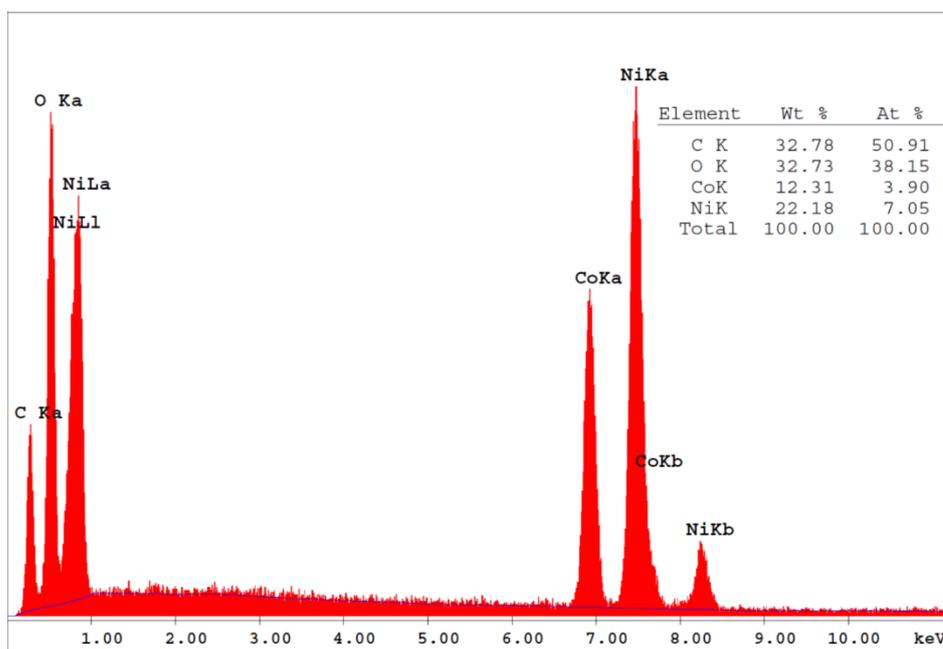

Figure 5.22. EDX spectrum of U-NiCo microspheres

SEM and TEM images of $\text{NiCo}_2\text{O}_4\text{-NiO}$ nanomaterials synthesized by using CTAC (C-NiCo) are demonstrated in Figure 5.23. Unlike U-NiCo, numerous nanoplates of C-NiCo are assembled to form a spherical structure. TEM images shown in Figure 5.23d,e reveal that nanoplates are assemblies of nanoparticles with average of $85 \text{ nm} \pm 10 \text{ nm}$. EDX analysis was also utilized to prove the presence of Co and Ni in the structure (Figure 5.24). Similar to U-NiCo, elemental mapping of C-NiCo hierarchical microspheres shows that Ni, Co and O are distributed homogeneously across the whole structure.

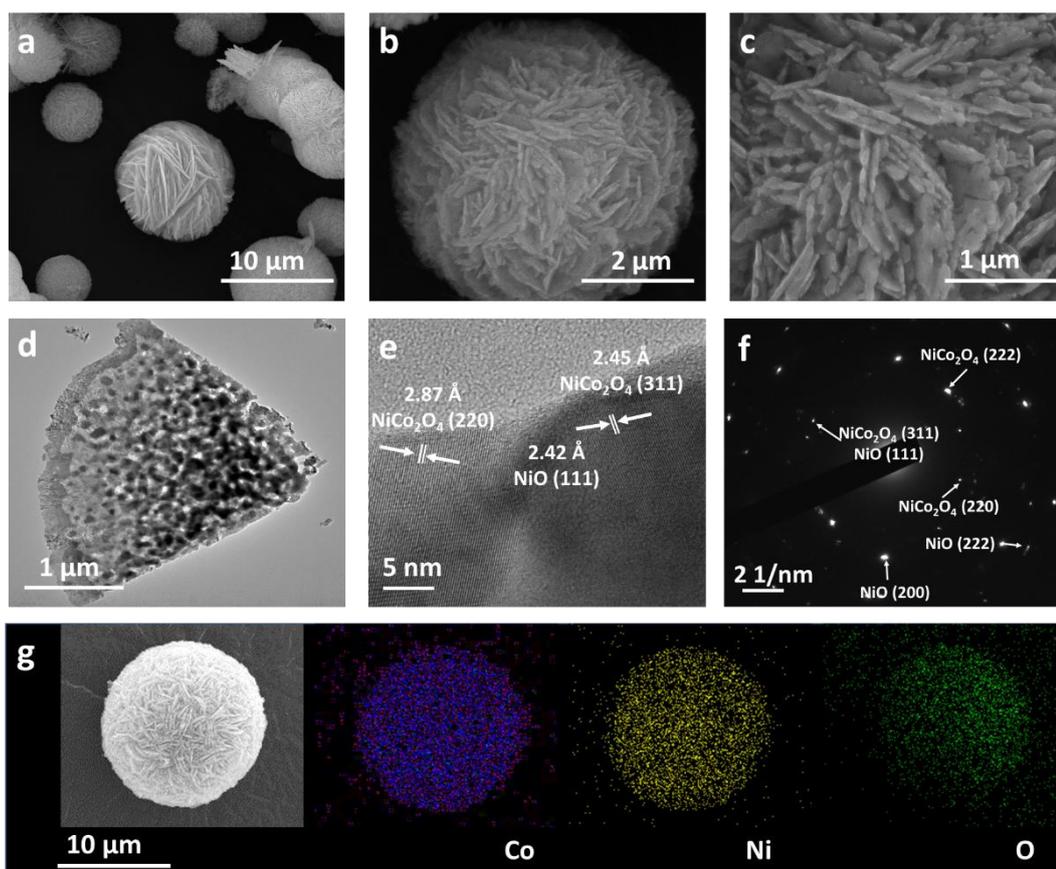

Figure 5.23. (a-c) SEM and (d-e) TEM images at different magnifications, (f) SAED pattern and (g) Element mapping (Co (blue), Ni (yellow), O (green)) of C-NiCo microspheres

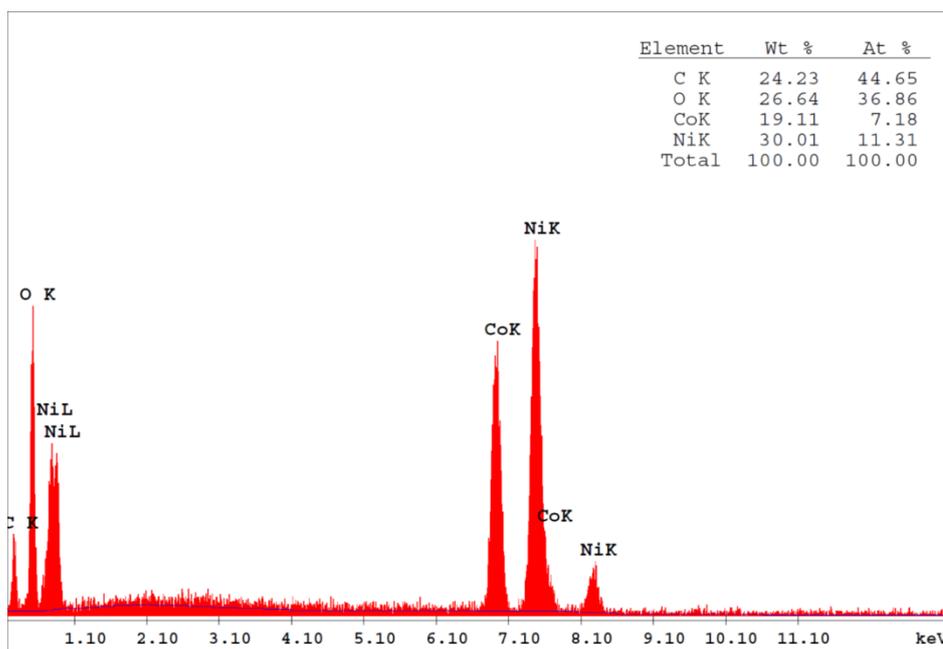

Figure 5.24. EDX spectrum of C-NiCo microspheres

XRD patterns of NiCo₂O₄-NiO microspheres are given in Figure 5.25. The patterns of both materials demonstrate peaks at 2θ values of 18.9°, 31.1°, 36.7°, 38.4°, 44.6°, 55.4°, 59.2°, 65.2° and 77.1° which were indexed to (111), (220), (311), (222), (400), (422), (511), (440) and (533) planes of NiCo₂O₄, respectively (PDF 01-073-1702). In addition, diffraction peaks located at 2θ values of 37.2°, 43.2°, 62.7°, 75.3° and 79.2° were assigned to (111), (200), (220), (311) and (222) planes of cubic NiO (PDF 01-071-1179), suggesting the formation of NiO along with spinel NiCo₂O₄. XRD peak analysis³⁸ was performed to estimate crystallite sizes which were calculated as ca. 17.8 nm and 28.9 nm for U-NiCo and C-NiCo, respectively. The diffraction peak at 43.2° (200) was used in the analysis. The crystallite sizes are slightly smaller than the sizes of particles measured by TEM analysis.

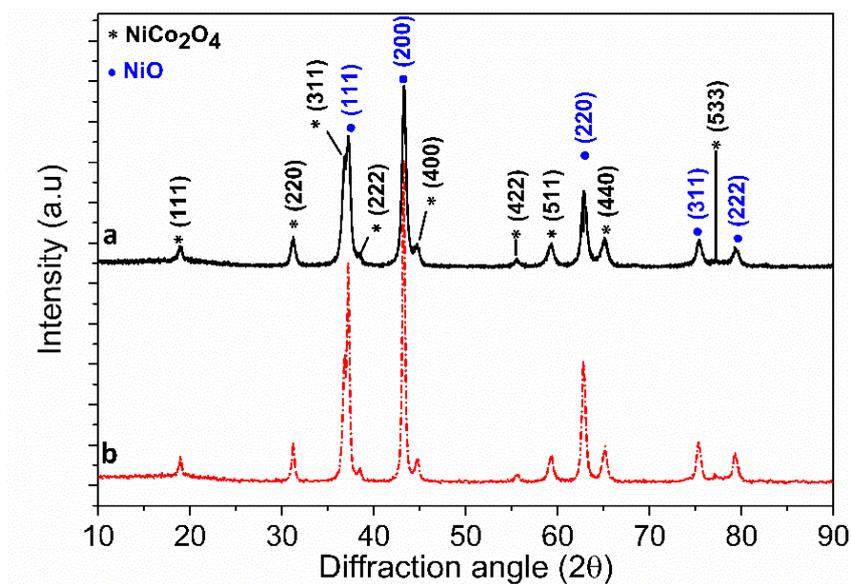

Figure 5.25. XRD patterns of (a) U-NiCo and (b) C-NiCo microspheres

Figures 5.26, 5.27 and 5.28 show the XPS spectra of $\text{NiCo}_2\text{O}_4\text{-NiO}$ microspheres. The survey spectra of both U- and C-NiCo reveal the presence of Co, Ni, O and C, which was used for calibration (Figure 5.26).

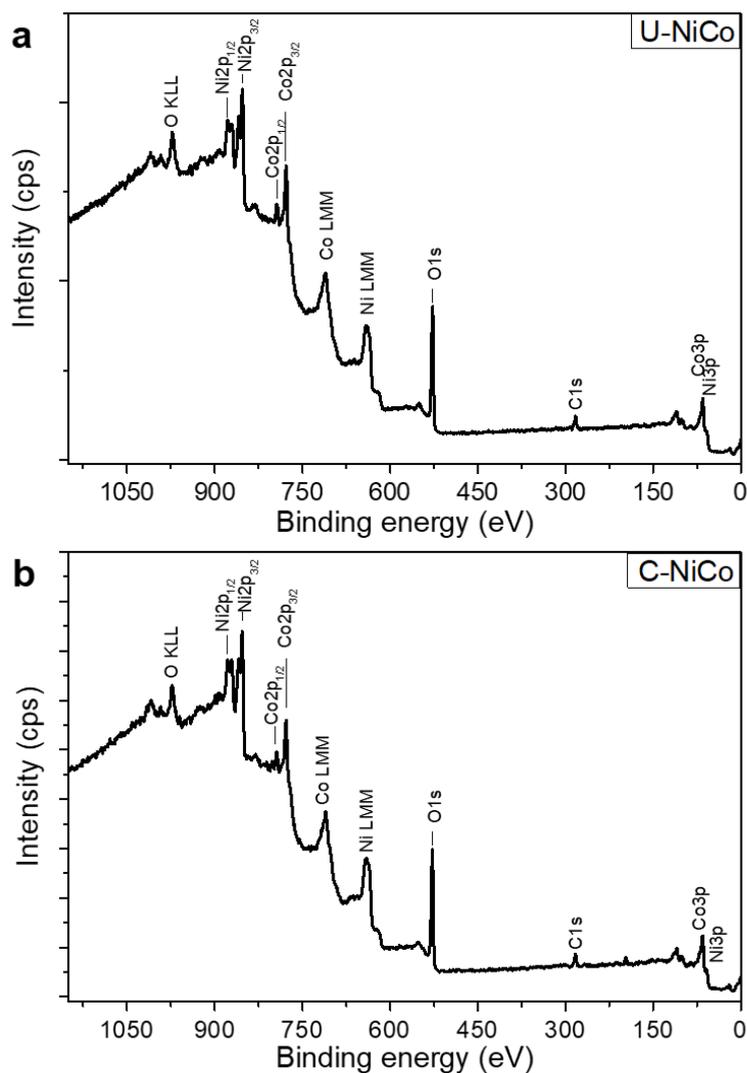

Figure 5.26. XPS Survey spectra of (a) U-NiCo and (b) C-NiCo microspheres

The Co 2p core-level spectra of U- and C-NiCo microspheres are given in Figure 5.27a and 5.28a. The peaks were fitted to two spin-orbit doublets at 777.9 eV and 793.0 eV corresponding to $2p_{3/2}$ and $2p_{1/2}$, respectively. Two bands under each Co 2p peak were observed by Gaussian fitting process. The peaks were assigned to Co^{2+} (777.4 eV and 792.5 eV) and Co^{3+} (778.7 eV and 794.1 eV) which agree well with the values reported in previous studies.^{23,29,56,83-86} The Ni 2p core-level spectrum exhibits two spin-orbit doublets at 852.1 eV and 870.1 eV with two shakeup satellite

peaks (Figure 5.27b and 5.28b). The fitted peaks at 851.9 eV and 869.6 eV were ascribed to Ni^{2+} while the ones at 853.8 eV and 871.5 eV were assigned to Ni^{3+} .^{56,84-86} The spectrum of O 1s shows two oxygen contributions which were ascribed to metal-oxygen bond (peak I at 527.5 eV) and oxygen species (i.e O_2^{2-} , OH^-) adsorbed onto the catalyst surface (peak II at 528.8 eV) suggesting the existence of low oxygen coordination sites in the materials (Figure 5.27c and 5.28c).^{23,29}

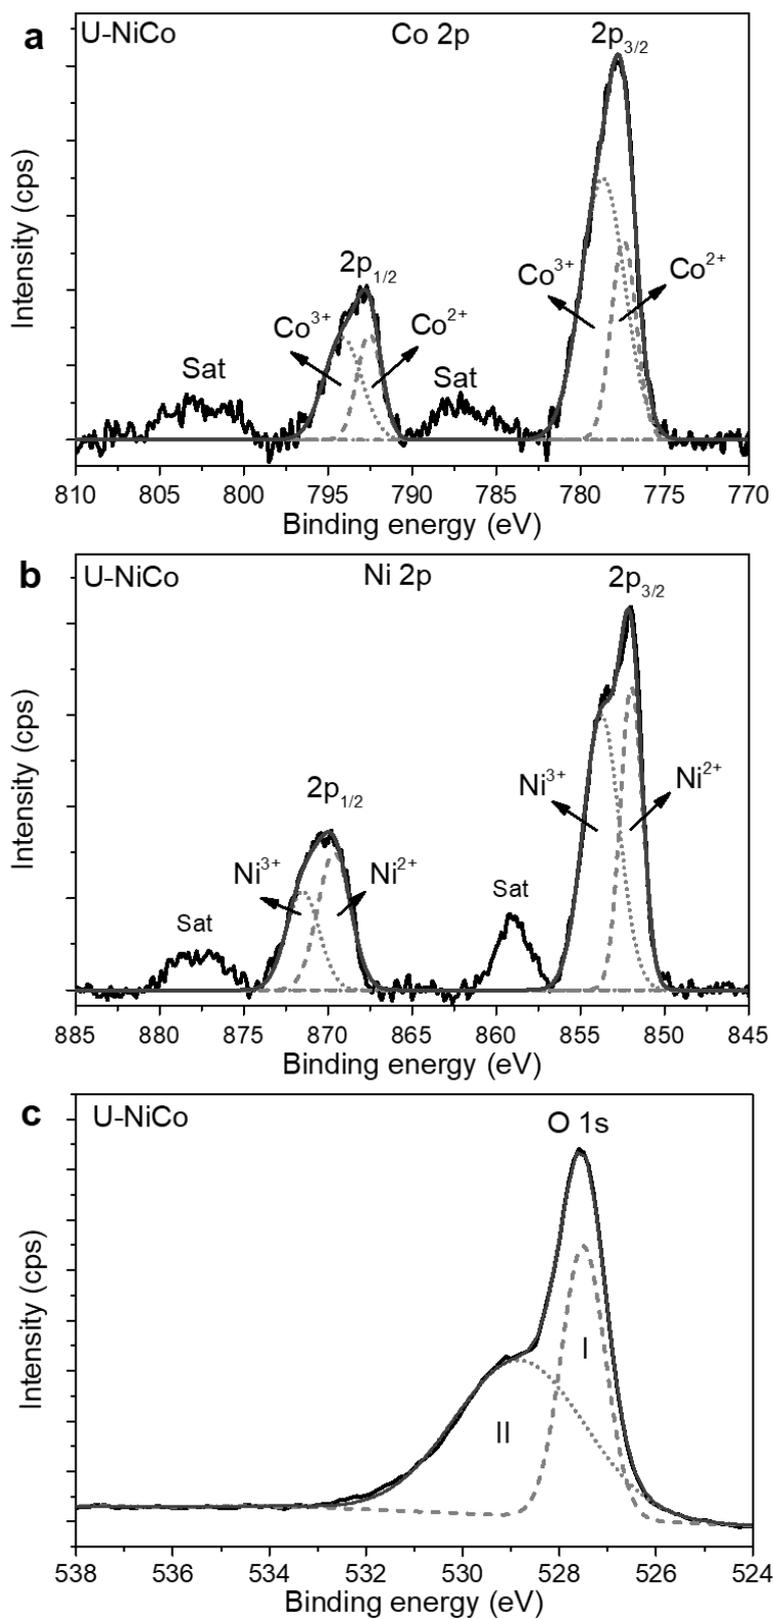

Figure 5.27. XPS (a) Co 2p, (b) Ni 2p and (c) O 1s spectra of U-NiCo microspheres

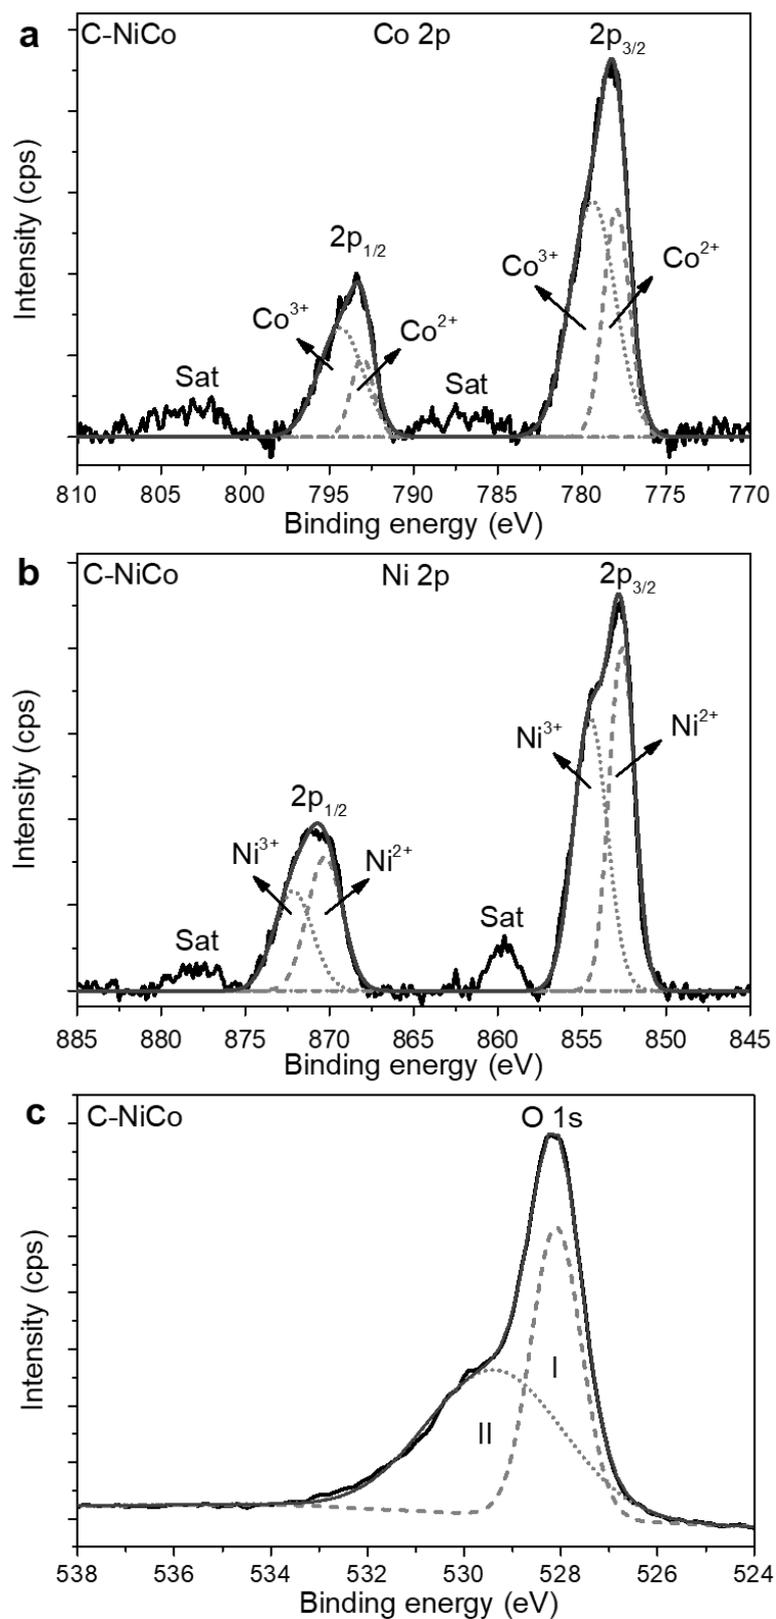

Figure 5.28. XPS (a) Co 2p, (b) Ni 2p and (c) O 1s spectra of C-NiCo microspheres

Elemental composition and mass percent of each element in the microspheres were investigated by ICP-OES. The amount of Co was found to be 28 wt% and 27 wt% in U-NiCo and C-NiCo, respectively. The amount of Ni in U-NiCo was determined as 53 wt%, whereas it was found as 57 wt% in C-NiCo. NiCo₂O₄:NiO mole ratio were calculated using ICP-OES data, and found to be 1:2.8 and 1:3.2 for U-NiCo and C-NiCo, respectively. N₂ adsorption-desorption analyses were performed to examine the BET surface areas and pore size of the synthesized nanomaterials. BET surface areas were determined as 41.3 m² g⁻¹ and 13.4 m² g⁻¹ for U-NiCo and C-NiCo, respectively. BET isotherms (Figure A.3) suggest the mesoporous nature of NiCo₂O₄-NiO microspheres with average pore sizes of 2.5 nm and 3.0 nm for U-NiCo and C-NiCo, respectively. Moreover, pore volume of U-NiCo was determined as 0.45 cm³ g⁻¹ while for C-NiCo it was 0.20 cm³ g⁻¹. Larger pore volume with smaller pore size suggest that U-NiCo nanomaterials possess higher number of pores than that of C-NiCo.

5.2 Electrochemical Activities of Transition Metal Oxide Nanomaterials for Water Oxidation Reaction

5.2.1 Electrochemical activity of CuCr₂O₄ nanoparticles

Being the first material investigated in this study, important parameters (i.e. preparation of the electrode, catalyst loading, and type of electrolyte) for electrocatalytic water oxidation reaction was determined with CuCr₂O₄ nanoparticles. Effect of carbon materials (Printex L6 (PL6), Super C65 (SC65), multiwalled carbon nanotube (MWCNT)) addition into catalyst solution as well as effect of carbon and Nafion[®] amount on onset potential and current density were studied (see Appendix). However, no significant difference was noted with the addition of carbon materials. During the preliminary measurements, optimum amount of Nafion[®] was determined as 19.0 μL. Hence, same amount of Nafion[®] was used throughout the study of electrochemical activities of other nanomaterials.

Electrochemical measurements were performed in two different electrolyte solution, namely 0.1 M sodium borate (pH:9.2) and 0.1 M KOH solution. Maximum current density value the catalyst could generate was 1.68 mA cm^{-2} at an overpotential of 830 mV with the use of sodium borate solution (Figure B.1 and Table B.1). Therefore, 0.1 M KOH solution was used in the investigation of electrochemical activities of nanomaterials for water oxidation reaction.

Figure 5.29a shows the polarization curve of CuCr_2O_4 nanoparticles along with that of bare GCE. CuCr_2O_4 nanoparticles exhibited an onset potential of 2.07 V (vs RHE) with an overpotential of 1.05 V to drive current density of 10 mA cm^{-2} (η_{10}). Both onset potential and η_{10} are very high indicating that CuCr_2O_4 nanoparticles are not very active in water oxidation reaction. Water oxidation kinetics of the nanoparticles were examined by fitting polarization curves to Tafel equation. Tafel slope was determined as 67 mV dec^{-1} (Figure 5.29b).

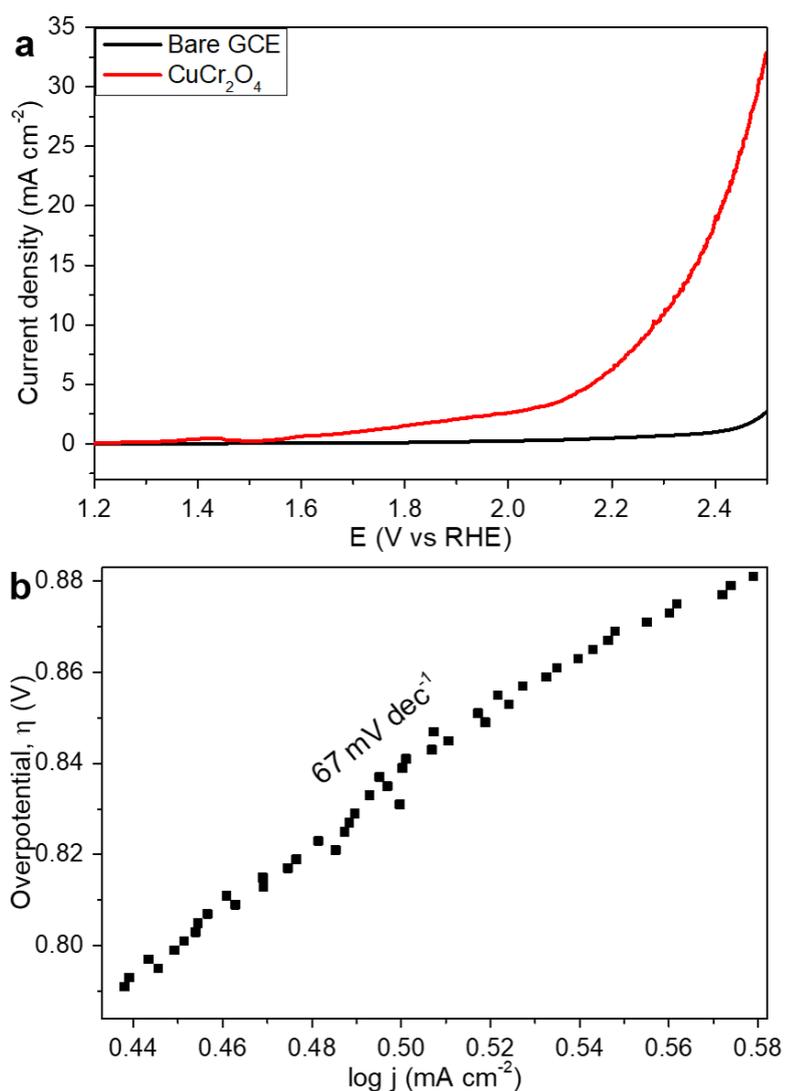

Figure 5.29. (a) Polarization curves of bare GCE and CuCr₂O₄ nanoparticles in 0.1 M KOH at a scan rate of 5 mV s⁻¹ and (b) The corresponding Tafel plot obtained from polarization curve

EIS was utilized to further investigate the kinetic properties of the prepared catalyst. Semicircles demonstrated in Figure 5.30 are associated with the charge transfer resistance (R_{ct}) at high frequencies. The diameter of the semicircle decreases with increasing overpotential, which indicates enhanced electrical conductivity as well as

faster charge transfer during oxygen evolution. R_{ct} of the electrode at onset potential was calculated as 76Ω by fitting to constant phase element (CPE) model.

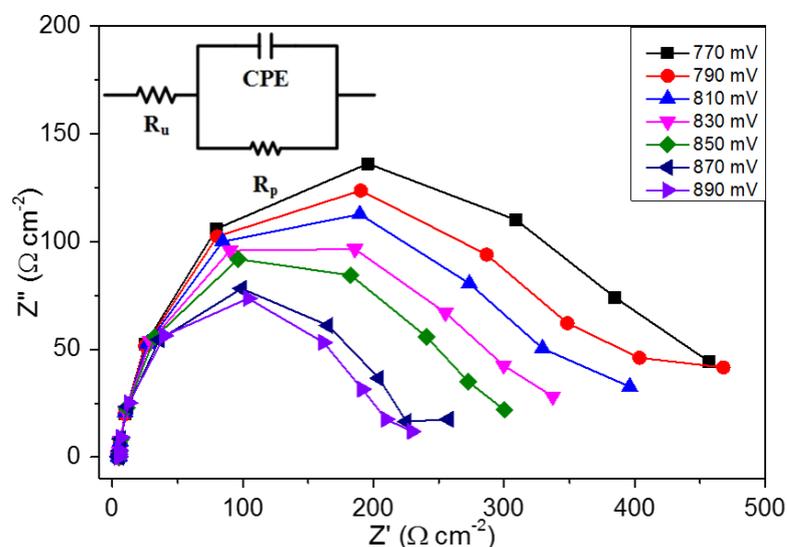

Figure 5.30. Nyquist plots of CuCr₂O₄ nanoparticles at various overpotential values in 0.1 M KOH

The durability of the nanoparticles was studied using chronopotentiometry ($j=10 \text{ mA cm}^{-2}$) for 3 h (Figure 5.31) and chronoamperometry ($\eta=1.10 \text{ V}$) for another 3 h (Figure 5.32). Figure 5.31a shows the polarization curves obtained before and after chronopotentiometry, while potential of time-dependent curve is given in Figure 5.31b. There is a slight decrease in the potential during the course of electrolysis. In addition, slight increase in both onset potential and overpotential ($\eta=1.12 \text{ V}$) at $j=10 \text{ mA cm}^{-2}$ were observed after electrolysis.

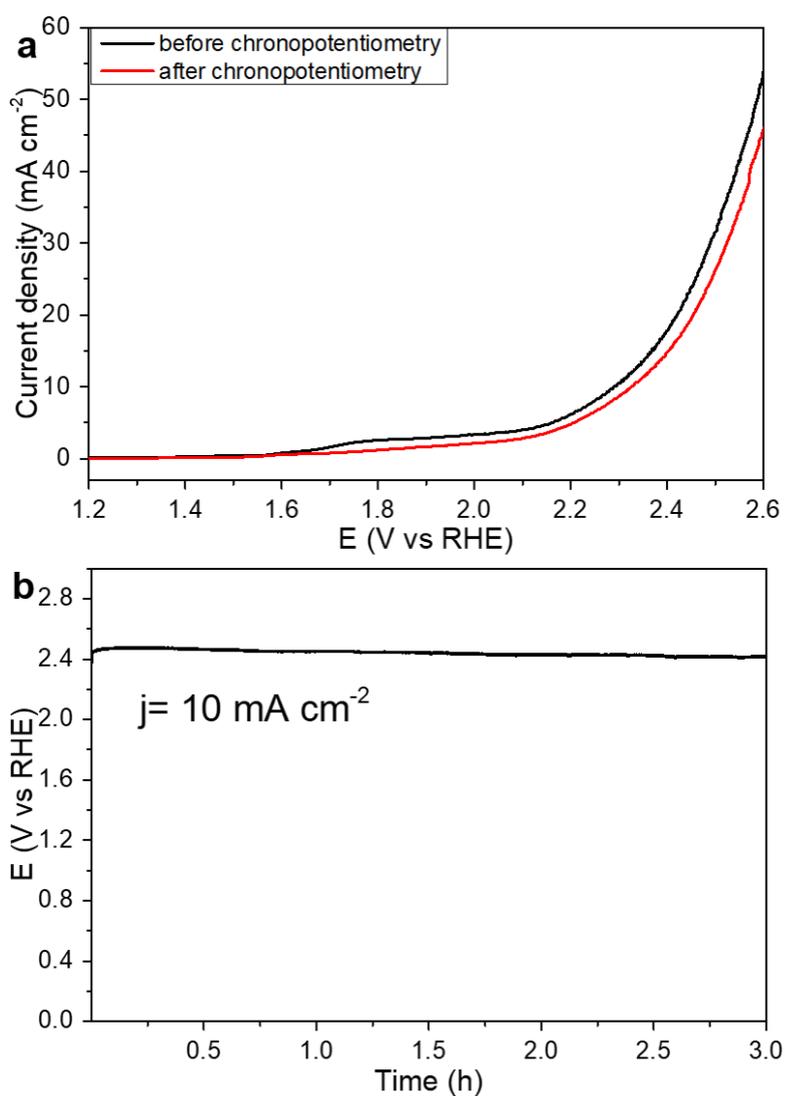

Figure 5.31. (a) Polarization curves before and after chronopotentiometric electrolysis at $j=10 \text{ mA cm}^{-2}$ and (b) the change in potential during chronopotentiometry in 0.1 M KOH

As shown in Figure 5.32b, the current density of 10 mA cm^{-2} was maintained for another 3 h. Even though CuCr_2O_4 nanoparticles do not exhibit very high electrocatalytic activity, both of the stability tests indicate good stability for water oxidation reaction when the required conditions are set.

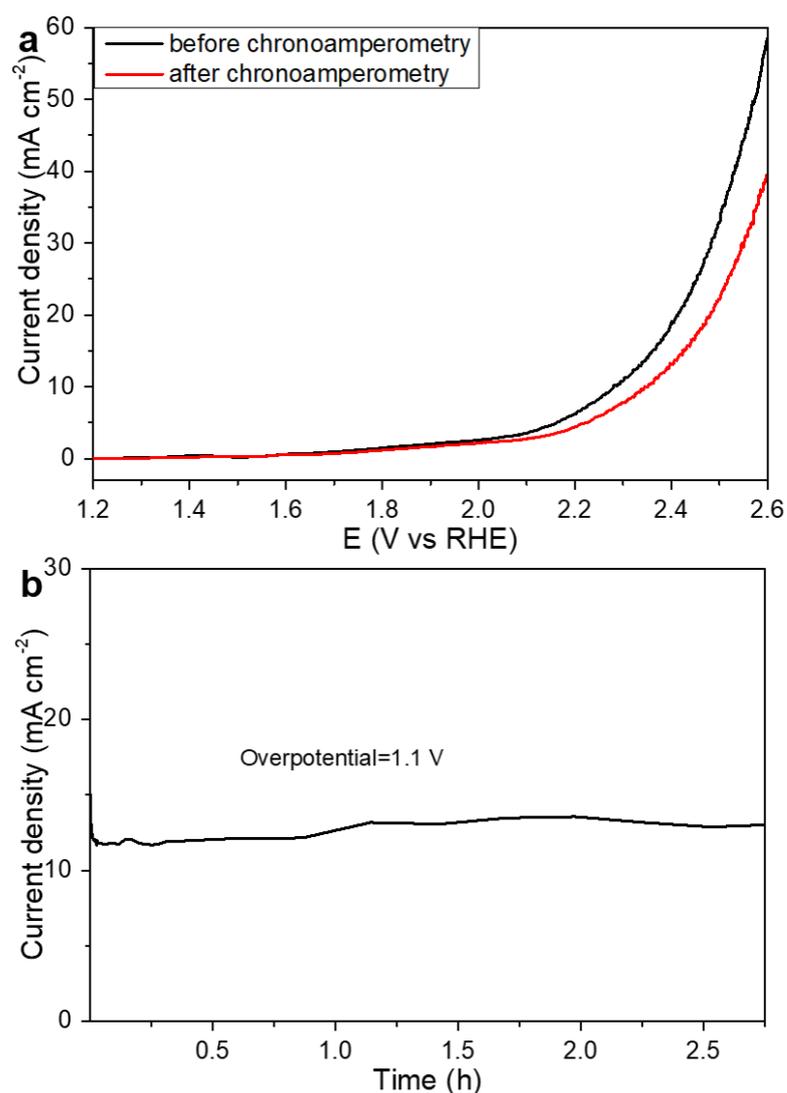

Figure 5.32. (a) Polarization curves before and after chronoamperometric electrolysis at $\eta=1.1$ V and (b) the change current density during chronoamperometry

5.2.2 Electrocatalytic activity of FeMnO₃ nanowires

The electrocatalytic activities of FTO substrates modified with FeMnO₃ nanowires were investigated towards water oxidation in alkaline medium (0.1 M KOH). FeMnO₃ modified FTO (FeMnO₃-FTO) was used as working electrode, and

evaluation of its performance was performed by studying polarization curves. For comparison, bare FTO electrode and RuO_2 were also tested under the same conditions and resulting voltammograms are depicted in Figure 5.33a. Inspection of the data reveals that FeMnO_3 -FTO demonstrates relatively high electrocatalytic activity for OER with an onset potential of 1.60 V vs RHE. Bare FTO, on the other hand, was found to exhibit almost no activity in the same medium. Although the onset potential of FeMnO_3 -FTO electrode was found to be higher than that of RuO_2 (1.45 V vs RHE), it is comparable to those of previously reported perovskite oxides especially CaMnO_3 (1.60 V vs RHE)¹⁵, $\text{LaFeO}_{3-\delta}$ (1.63 V vs RHE)⁸⁷, $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ (1.57 V vs RHE)¹⁸ and S-doped CaMnO_3 (1.60 V vs RHE)¹⁶.

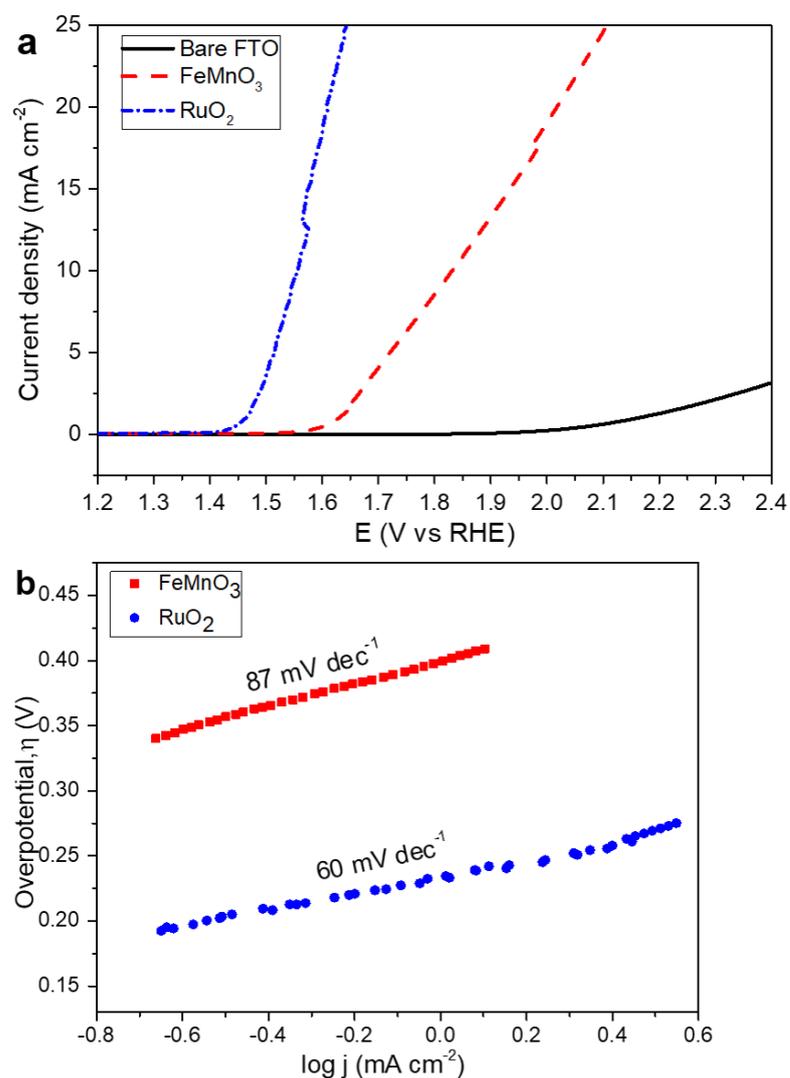

Figure 5.33. (a) Polarization curves bare GCE, FeMnO₃ nanowires and RuO₂ in 0.1 M KOH at a scan rate of 5 mV s⁻¹ and (b) The corresponding Tafel plots obtained from polarization curves

The water oxidation activity of FeMnO₃ nanowires was also tested by using the overpotentials required to drive anodic current densities of 5 mA cm⁻² (η_5) and 10 mA cm⁻² (η_{10}). For FeMnO₃-FTO, the η_5 and η_{10} were measured as 490 mV and 600 mV, respectively. The results obtained from FeMnO₃-FTO are summarized in Table 3.1, as well as the ones of some reported catalysts, for comparison.

The water oxidation kinetics of FeMnO₃ nanowires were evaluated by fitting Tafel plot from polarization curves (Figure 5.33b). Tafel slope was estimated by employing the Tafel equation and was determined as 87 mV dec⁻¹ for FeMnO₃-FTO. The slope was found to be much smaller than the ones of recently reported OER electrocatalysts such as La_{0.45}Sr_{0.45}Mn_{0.9}Fe_{0.1}O_{3-δ} (139 mV dec⁻¹)¹⁹, CaMnO₃ (197 mV dec⁻¹) and Ca₂Mn₂O₅ (149 mV dec⁻¹)¹⁵ indicating faster OER kinetics on FeMnO₃-FTO. Tafel slope of RuO₂ was found to be 60 mV dec⁻¹, and agree well with the ones reported in the literature (i.e. 69 mV dec⁻¹⁵, 70 mV dec⁻¹⁴, 90 mV dec⁻¹²).

Table 5.1 Summary of the data of some recently reported representative water oxidation electrocatalysts and FeMnO₃ nanowires in alkaline medium

	Onset (RHE)	η (@10 mA cm ⁻²)	Tafel slope (mV dec ⁻¹)	Medium	REF
FeMnO ₃	1.60	600	87	0.1 M KOH	This work ¹¹
CaMnO ₃	1.6	-	197	0.1 M KOH	¹⁵
Ca ₂ Mn ₂ O ₅	1.5	-	149	0.1 M KOH	¹⁵
LaFeO _{3-δ}	1.63	465	50	1.0 M KOH	⁸⁷
La _{0.8} Sr _{0.2} MnO ₃ *	1.57	985	-	0.1 M KOH	¹⁸
S-doped CaMnO ₃	1.6	550	-	0.1 M KOH	¹⁶
La _{0.45} Sr _{0.45} Mn _{0.9} Fe _{0.1} O _{3-δ}	-	340	139	0.1 M KOH	¹⁹
BaMnO ₃	-	740 (η3)	-	0.1 M KOH	²⁰
BaMnO ₃ @C	-	740 (η14)	-	0.1 M KOH	²⁰
CaMnO _{2.77}	1.4	570 (η4)	-	1.0 M KOH	¹⁷
RuO ₂	1.45	326	60	0.1 M KOH	This work

ECSA and RF values, which are directly proportional to the number of surface active sites were also determined to better analyze the electrocatalytic activity of the FeMnO₃ nanowires. CVs recorded at non-Faradaic potential range with various scan rates are given in Figure 5.34 along with the plot of double-layer charging current

(at 1.27 V vs RHE) versus scan rate. The slope of the plot, which gives the C_{dl} value of FeMnO_3 nanowires has been found as 1.78 mF. The ECSA and RF values were calculated as 29.6 cm^2 and 59.2, respectively. The high values of ECSA and RF is consistent with the large surface area of the nanowires. Moreover, mass activity and specific activity of FeMnO_3 nanowires were calculated at an overpotential of 600 mV and determined to be as 10.8 A g^{-1} and $0.17 \text{ A cm}^{-2}_{\text{ECSA}}$, respectively.

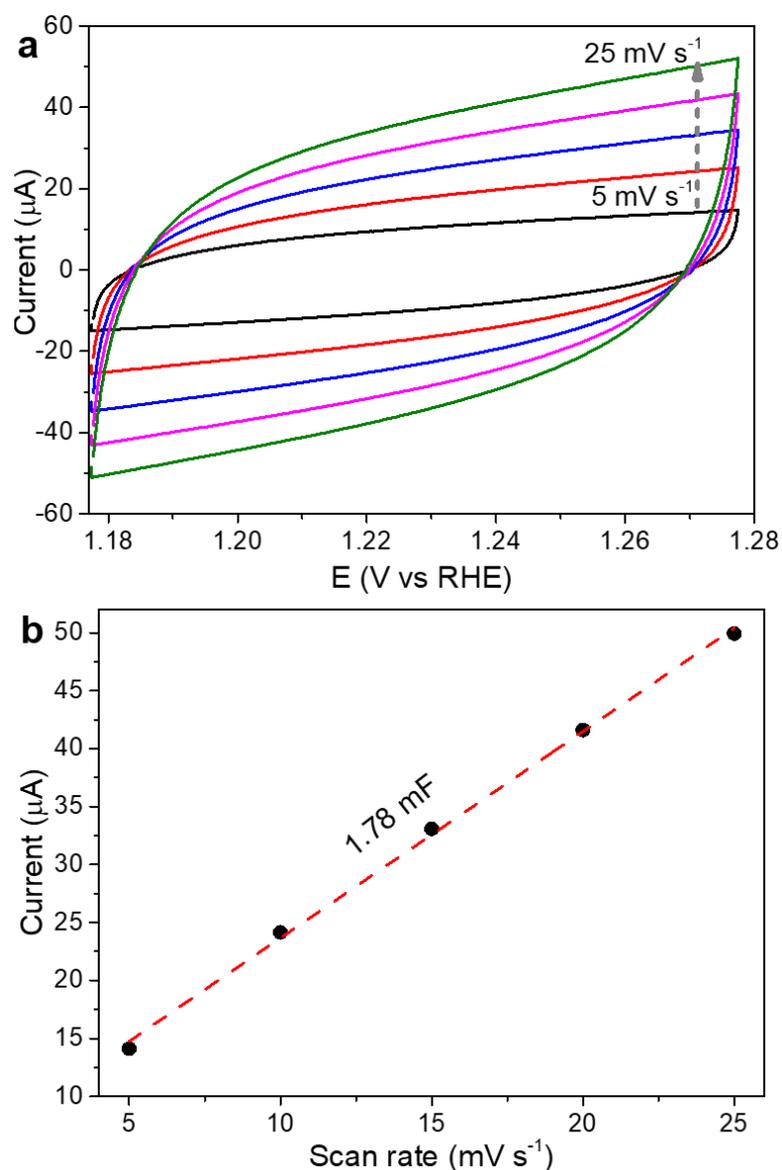

Figure 5.34. (a) CVs of FeMnO_3 nanowires measured at different scan rates from 5 to 25 mV s^{-1} and (b) Plot of current at 1.27 V (vs RHE) vs scan rate

EIS was also performed at different overpotentials to further investigate the kinetic properties of the prepared catalyst in water oxidation reaction. The Nyquist plots of FeMnO₃-FTO consist of semicircles, which fit to CPE model (see inset of Figure 5.35), where R_u and R_p correspond to solution resistance and charge transfer resistance (R_{ct}), respectively. The semicircles are associated with R_{ct} at high frequency region. The diameter of the semicircle decreases as the overpotential increases, which indicates enhanced electrical conductivity as well as faster charge transfer during water oxidation process.

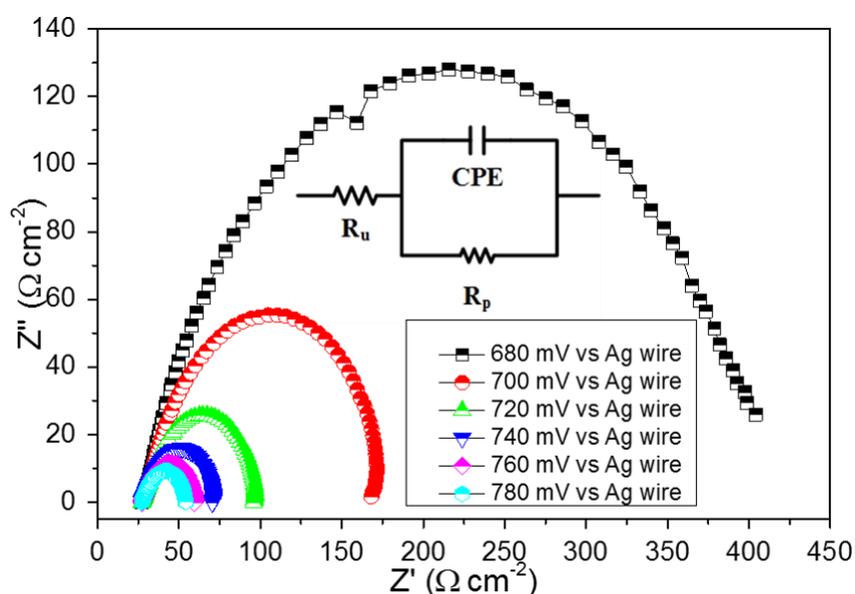

Figure 5.35. Nyquist plots for the FeMnO₃-FTO electrodes at different overpotentials

The durability of the modified FTO electrode was also tested in order to evaluate the water oxidation performance of the electrocatalyst for practical applications. Constant potential electrolysis was employed at overpotential of 650 mV for 10800 s in 0.1 M KOH. The polarization curves recorded before and after constant potential electrolysis are shown in Figure 5.36a. A slight shift to the higher potential

values in both onset potential (from 1.60 V to 1.70 V) and overpotential for 10 mA cm^{-2} (from 600 mV to 718 mV) was observed after 10800 s constant potential electrolysis.

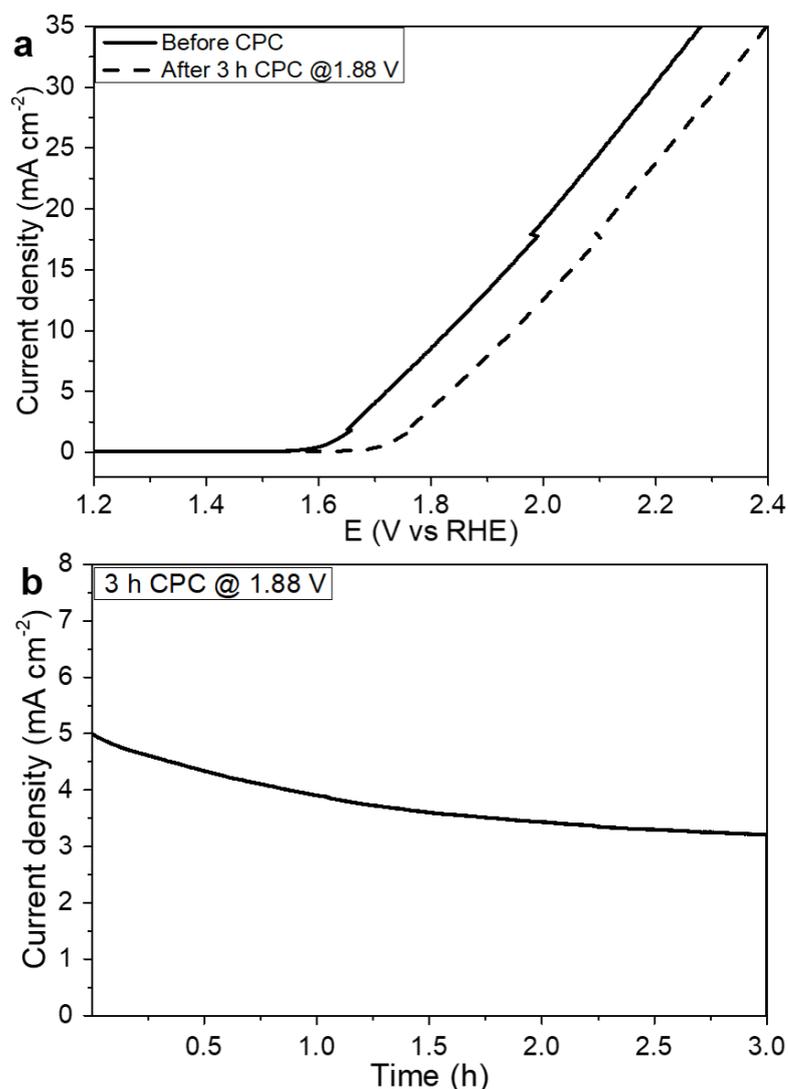

Figure 5.36. (a) Polarization curve of FeMnO₃-FTO electrode before and after controlled potential electrolysis at overpotential corresponding to initial current density of 5 mA cm^{-2} and (b) Change in current density during electrolysis in 0.1 M KOH

The water oxidation activity of FeMnO_3 nanowires was also evaluated by measuring the volume of O_2 gas produced during the electrolysis of water. The measurement was performed using the modified FTO electrode, FeMnO_3 -FTO, as the anode in a Hoffman electrolysis set-up. The volume of O_2 released was monitored for 3600 s at a constant current of 5 mA at room temperature (Figure 5.37). The Faradaic yield of FeMnO_3 -FTO for O_2 production was measured as >95% after the transfer of 18 C of charge. The amount of O_2 obtained is very close to the theoretical yield suggesting FeMnO_3 nanowires are promising candidates for OER electrocatalyst.

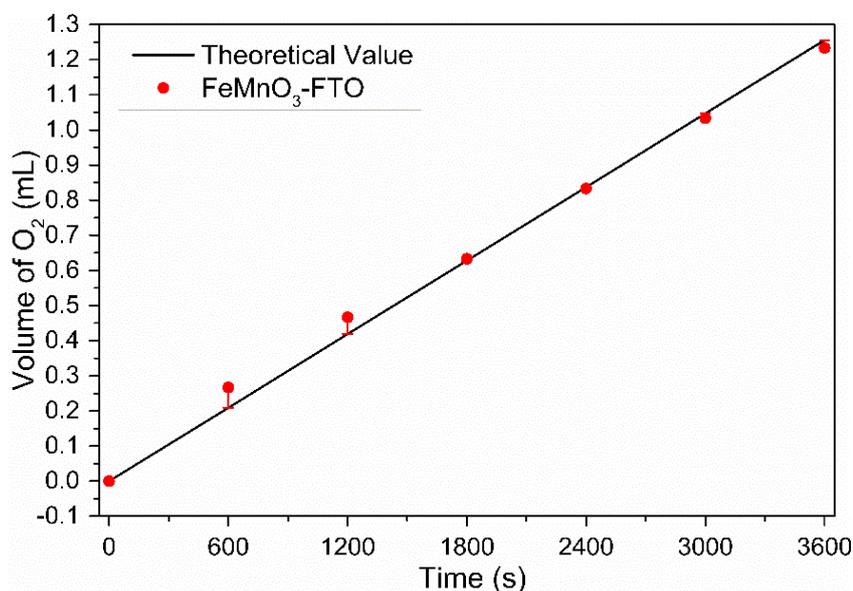

Figure 5.37. Plot of O_2 volume vs time during the electrolysis of water using FeMnO_3 -FTO electrode

5.2.3 Electrocatalytic activity of NiFe_2O_4 -NiO nanoparticles

The electrocatalytic activity of NiFe_2O_4 -NiO nanoparticles for water oxidation was investigated by LSV in alkaline medium, at room temperature. Polarization curve of GCE decorated with NiFe_2O_4 -NiO nanoparticles as well as the ones obtained for

RuO₂ and bare GCE are demonstrated in Figure 5.38a. Onset potential of 1.57 V (vs RHE) was observed for NiFe₂O₄-NiO nanoparticles suggesting a significant enhancement in the catalytic performance of GCE through alteration with nanoparticles. This value is comparable to or even smaller than those of previously reported similar structures such as NiO/NiFe₂O₄ nanorods (1.46 V vs RHE)³⁰, NiO/NiFe₂O₄ (1.50 V vs RHE)⁸⁸, NiO/NiFe₂O₄-rGO (1.436 V vs RHE)⁷¹, NiFe₂O₄ nanofibers (1.67 V vs RHE) and NiFe₂O₄ nanoparticles (1.70 V vs RHE)²². Overpotential required to generate current density of 10 mA cm⁻² (η_{10}) or even higher values is another essential parameter in the assessment of electrocatalytic activity of the nanomaterial. NiFe₂O₄-NiO nanoparticles can drive current densities of 10 and 20 mA cm⁻² at overpotentials of 453 mV and 502 mV, respectively. On the other hand, RuO₂ can reach the same current densities at η_{10} =326 mV and η_{20} =380 mV. Nonetheless, it is also noteworthy at higher current densities (i.e 60 mA cm⁻²) the activity of NiFe₂O₄-NiO becomes quite similar to that of RuO₂. RuO₂, for instance, produce current density of 60 mA cm⁻² at an overpotential of 729 mV whereas NiFe₂O₄-NiO nanoparticles reach the same current density value at 760 mV. The most likely reason for this observation is the low stability of RuO₂ in alkaline medium under high anodic potentials, at which RuO₂ has been reported to oxidize to form RuO₄ and dissolve in solution.^{6,89} The electrocatalytic activity results of NiFe₂O₄-NiO together with the ones of previously reported catalysts are summarized in Table 5.2.

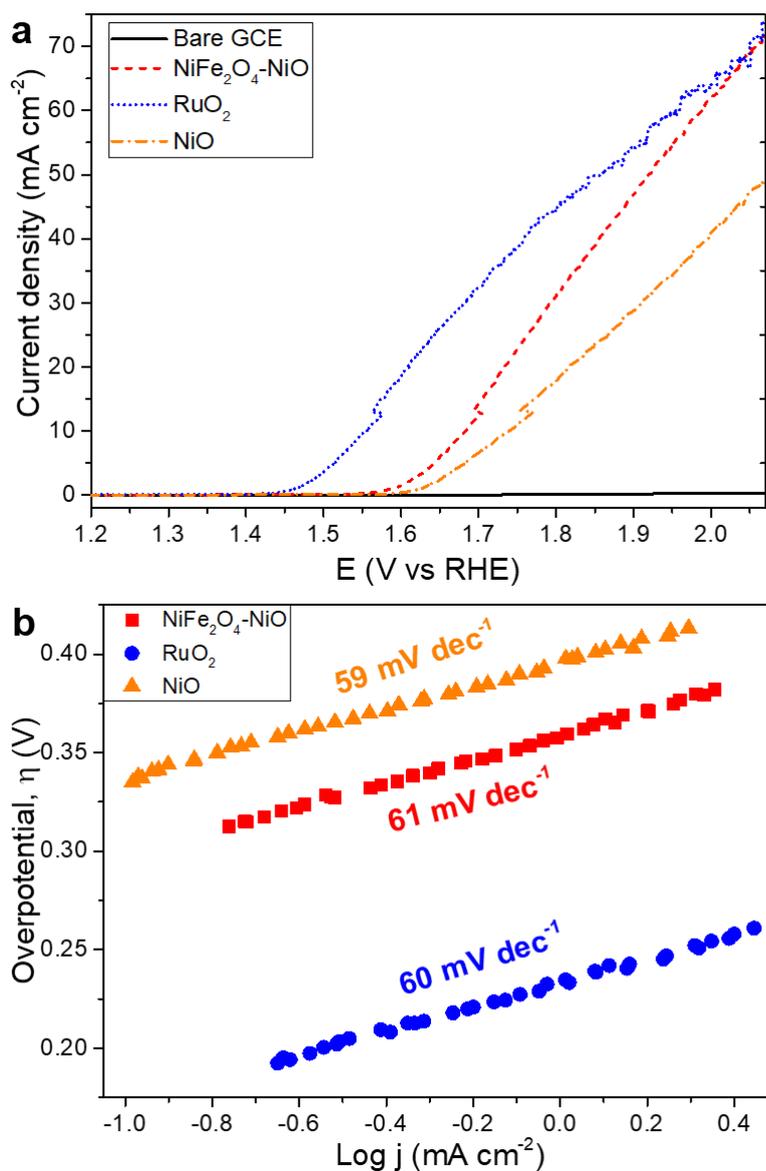

Figure 5.38. (a) Polarization curves of bare GCE, NiFe₂O₄-NiO nanoparticles, NiO and RuO₂ in 0.1 M KOH at a scan rate of 5 mV s⁻¹ and (b) The corresponding Tafel plot obtained from polarization curves

Tafel slope, which can be obtained by fitting the linear part of polarization curve to Tafel equation, gives valuable insights about the electrocatalytic performance of the catalyst. Figure 5.38b shows the Tafel plots of NiFe₂O₄-NiO nanoparticles together with that of NiO and RuO₂, for comparison. Tafel slope of NiFe₂O₄-NiO

nanoparticles was calculated as 61 mV dec^{-1} , which is comparable to or even smaller than those of similar structure such as NiO/NiFe₂O₄ hollow cages (58.5 mV dec^{-1})⁷⁶, NiFe₂O₄ nanotubes (53.3 mV dec^{-1})²¹, NiFe₂O₄/MWCNT (93 mV dec^{-1})⁹⁰, NiFe₂O₄/CNT (70 mV dec^{-1})⁹¹, NiFe₂O₄ nanofibers ($98.22 \text{ mV dec}^{-1}$) and NiFe₂O₄ nanoparticles ($243.68 \text{ mV dec}^{-1}$)²². In addition, Tafel slope of RuO₂ was determined 60 mV dec^{-1} pointing out that NiFe₂O₄-NiO nanoparticles exhibit comparable water oxidation kinetics to benchmark RuO₂ and previously reported nickel-iron oxide materials.

Table 5.2 Summary of the data for some recently reported representative water oxidation electrocatalysts and NiFe₂O₄-NiO nanoparticles

	Onset (RHE)	η_5 (mV)	η_{10} (mV)	Tafel slope (mV/dec)	Medium	REF

Number of active sites on nanomaterials' surface play a crucial role in catalyst activity. Therefore, ECSA and RF, which are directly proportional to the number of active sites are also used for the evaluation of the electrocatalytic activity. ECSA can be estimated by C_{dl}. CVs at non-Faradaic potential range are recorded at various scan

rates to determine the C_{dl} of NiFe₂O₄-NiO nanomaterials (Figure 5.39). The slope of double-layer charging current (at 1.27 V vs RHE) versus scan rate plot gives the C_{dl} value of the catalyst. NiFe₂O₄-NiO nanoparticles have C_{dl} value of 0.061 mF and ECSA of 1.02 cm². In addition, RF value was determined as 14.6. Mass activity and specific activity of NiFe₂O₄-NiO nanoparticles was calculated at an overpotential of 760 mV and found as 150 A g⁻¹ and 4.12 mA cm⁻²_{ECSA} while they were calculated as 165 A g⁻¹ and 0.23 mA cm⁻²_{ECSA} for RuO₂, respectively. Mass activity value obtained for NiFe₂O₄-NiO nanoparticles is very close to that of RuO₂ verifying the comparable electrocatalytic activity of them.

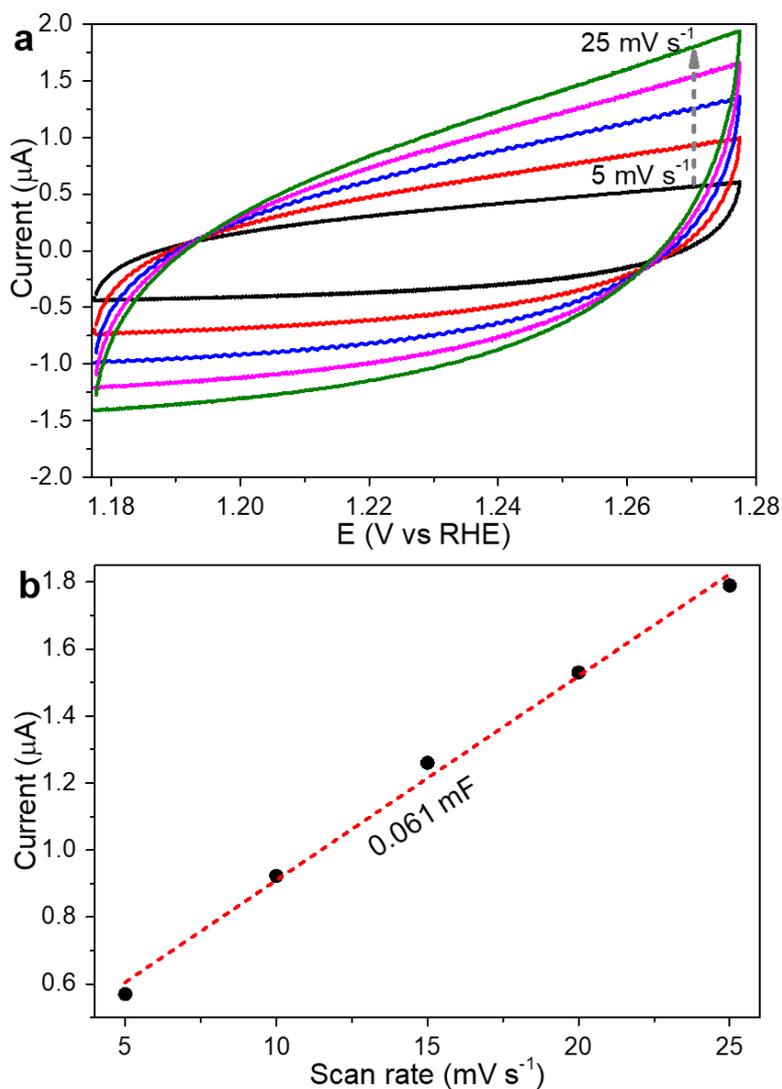

Figure 5.39. (a) CVs of NiFe₂O₄-NiO nanoparticles measured at different scan rate from 5 to 25 mV s⁻¹ and (b) Plot of current at 1.27 V (vs RHE) vs scan rate

The kinetic properties of NiFe₂O₄-NiO nanoparticles further investigated by EIS. Nyquist plots of the catalyst obtained at various overpotentials are given in Figure 5.40. The semicircles were fitted to CPE model, where solution resistance and charge transfer resistance (R_{ct}) are denoted as R_u and R_p , respectively. As the applied overpotential increase, a decrease in diameter of the semicircles is observed implying

the reduction of charge transfer resistance. Improvement of the electrical conductivity with lower R_{ct} , and thus easier charge transfer leads to enhanced catalytic activity of NiFe₂O₄-NiO nanoparticles during water oxidation reaction.

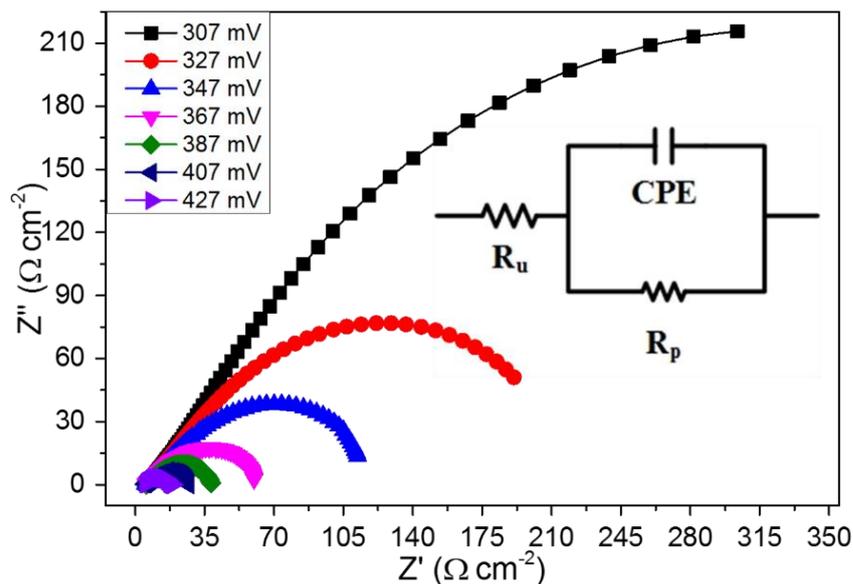

Figure 5.40. Nyquist plots of NiFe₂O₄/NiO nanoparticles at various overpotentials (inset shows the equivalent circuit diagram)

The assessment of NiFe₂O₄-NiO nanoparticles' stability was done by employing controlled potential coulometry in 0.1 M KOH solution. Overpotential of 415 mV was applied for 18000 s and polarization curves were recorded before and after electrolysis (Figure 5.41). A very slight increase in η_{10} (453 mV to 470 mV) was recorded while no change was observed on the onset potential signifying high stability of the synthesized nanomaterials during water oxidation.

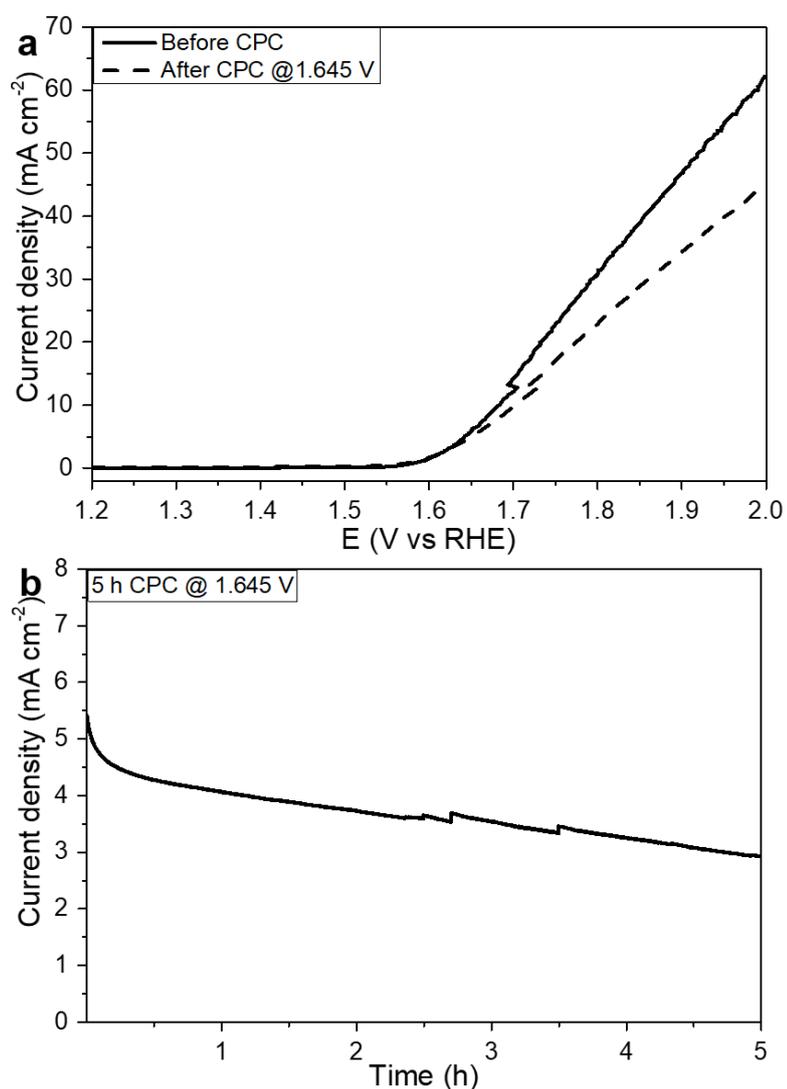

Figure 5.41. (a) Polarization curves of NiFe₂O₄-NiO nanoparticles recorded before and after controlled potential electrolysis at overpotential corresponding to initial current density of 5 mA cm⁻² and (b) Change in current density during electrolysis in 0.1 M KOH

5.2.4 Electrocatalytic activities of NiCo₂O₄-NiO microspheres

The electrocatalytic activities of NiCo₂O₄-NiO microspheres towards water oxidation reaction were evaluated using LSV. GCE modified with NiCo₂O₄-NiO

microspheres were used as working electrodes and the electrochemical measurements were performed in alkaline medium (0.1 M KOH) at room temperature. Figure 5.42a shows the resulting polarization curves as well as the ones obtained for bare RuO₂, Co₃O₄, NiO and GCE. Inspection of the data revealed that the electrocatalytic performance of GCE was significantly improved upon modification with NiCo₂O₄-NiO. The onset potentials of U-NiCo and C-NiCo were found to be 1.56 V and 1.57 V (vs RHE), respectively. These values are comparable to or even smaller than those of similar previously reported materials such as NiCo₂O₄ nanowires (1.56 V vs RHE)²⁶, NiCo₂O₄ (1.63 V vs RHE)²⁵, NiCo₂O₄ (1.66 V vs RHE)²⁹, NiCo₂O₄-NiO nanosheets (1.59 V vs RHE)²⁹ and MOF-derived NiCo₂O₄-NiO (1.58 V vs RHE)⁸⁶. Although U-NiCo and C-NiCo exhibit similar onset potentials, differences in overpotentials to drive the same catalytic current densities were noted. U-NiCo can generate current densities of 10 mA cm⁻² (η_{10}) and 20 mA cm⁻² (η_{20}) at overpotentials of 387 mV and 410 mV, respectively. For C-NiCo, on the other hand, η_{10} and η_{20} were measured as 430 mV and 467 mV, respectively. As these results suggest, U-NiCo exhibits better electrocatalytic activity than C-NiCo. The activities of NiCo₂O₄-NiO microspheres were also compared to that of RuO₂ under the same conditions. RuO₂ demands overpotentials of 326 mV and 380 mV to reach 10 and 20 mA cm⁻². However, it is also important to note that U-NiCo demonstrates better electrocatalytic performance than RuO₂ at higher current densities (i.e. current densities > 30 mA cm⁻²) (Figure 3.32a). For instance, U-NiCo can generate current density of 50 mA cm⁻² at an overpotential of 518 mV while RuO₂ requires 622 mV to reach the same current density value. As mentioned in NiFe₂O₄-NiO nanomaterials, the reason for this observation is the low stability of RuO₂ in alkaline medium under high anodic potentials, at which RuO₂ has been reported to oxidize to form RuO₄ and dissolve in solution.^{6,89} In addition, RuO₂ is known to be the best electrocatalyst for water oxidation reaction, and thus it is expected to observe high amount of gas formation. At higher applied potential, the gas bubble formation increases and accumulates on to electrode surface blocking the electrode which has a very small surface area (0.07 cm²). The observed lower current

density at higher potential for RuO₂ is due to this gas accumulation on the electrode surface. The results obtained from NiCo₂O₄-NiO microspheres are summarized in Table 5.3, along with the ones of previously reported similar catalysts, for comparison.

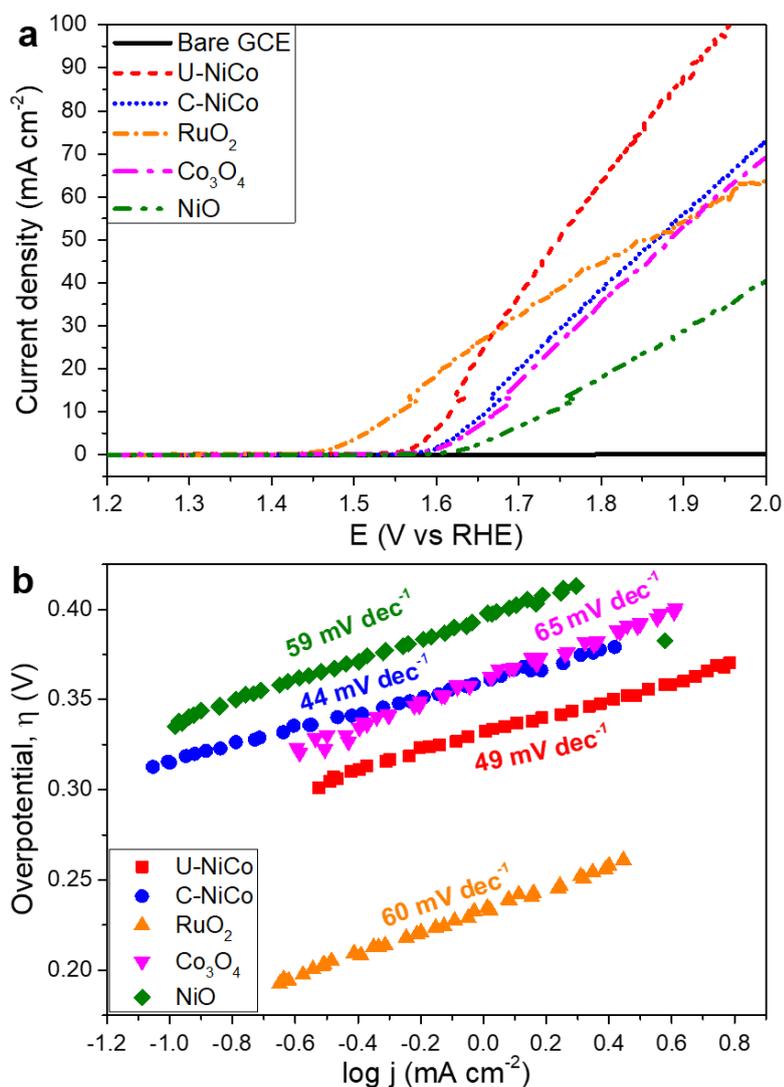

Figure 5.42. (a) Polarization curves of bare GCE, NiCo₂O₄-NiO microspheres, RuO₂, Co₃O₄ and NiO in 0.1 M KOH at a scan rate of 5 mV s⁻¹ and (b) The corresponding Tafel plots obtained from polarization curves

The water oxidation kinetics of NiCo₂O₄-NiO microspheres were elucidated by fitting the linear part of polarization curves to Tafel equation. Tafel slopes of U-NiCo and C-NiCo were determined as 49 and 44 mV dec⁻¹, respectively (Figure 5.42b). The slopes of NiCo₂O₄-NiO microspheres were calculated as smaller than the ones of both supported and free-standing nickel-cobalt oxide electrocatalysts such as MOF-derived NiCo₂O₄-NiO (49 mV dec⁻¹) and MOF-derived NiO-NiCo₂O₄-rGO (66 mV dec⁻¹)⁸⁶, NiCo₂O₄-NiO nanosheets (61 mV dec⁻¹)²⁹, NiCo₂O₄ nanoframes (82 mV dec⁻¹)⁵⁶, NiCo₂O₄-NiO nanocrystals (79 mV dec⁻¹)⁸⁵ and NiCo₂O₄ nanowires (60 mV dec⁻¹)²⁶. For comparison, Tafel slope of RuO₂ and Co₃O₄ were determined as 60 and 65 mV dec⁻¹, respectively. These results verify that U-NiCo and C-NiCo microspheres demonstrate faster water oxidation kinetics than benchmark RuO₂, Co₃O₄ and previously reported nickel cobalt oxide catalysts in different morphologies and/or on various supports.

Table 5.3 Summary of some recently reported representative water oxidation electrocatalysts and NiCo₂O₄-NiO microspheres

	Onset (RHE)	η_{10} (mV)	η_{50} (mV)	Tafel slope (mV/dec)	Medium	REF
U-NiCo₂O₄-NiO	1.56	387	518	49	0.1 M KOH	This work¹⁴
C-NiCo₂O₄-NiO	1.57	430	638	44	0.1 M KOH	This work¹⁴
NiO/NiCo ₂ O ₄ nanosheets	1.59	360	-	61	1.0 M NaOH	²⁹

Further evaluation of the polarization curve demonstrates a broad oxidation peak at ca. 1.4 V (vs. RHE) suggesting the formation of active species; NiOOH and CoOOH during water oxidation (Figure 5.43).^{30,83,85,92} It has been reported that oxidation of Ni²⁺ in NiO and NiCo₂O₄ lead to formation of NiOOH (NiO + OH⁻ → NiOOH + e⁻) along with CoOOH (NiCo₂O₄ + OH⁻ → NiOOH + 2CoOOH + e⁻) in alkaline medium.^{30,83,85,92} Thus, area of the observed oxidation peak affirms the formation of these active species during catalysis, and associate with the water oxidation performance of the catalyst. Therefore, comparison of the oxidation peak intensity

for U-NiCo and C-NiCo suggest that water oxidation efficiency of U-NiCo with higher peak intensity is better than the one of C-NiCo.

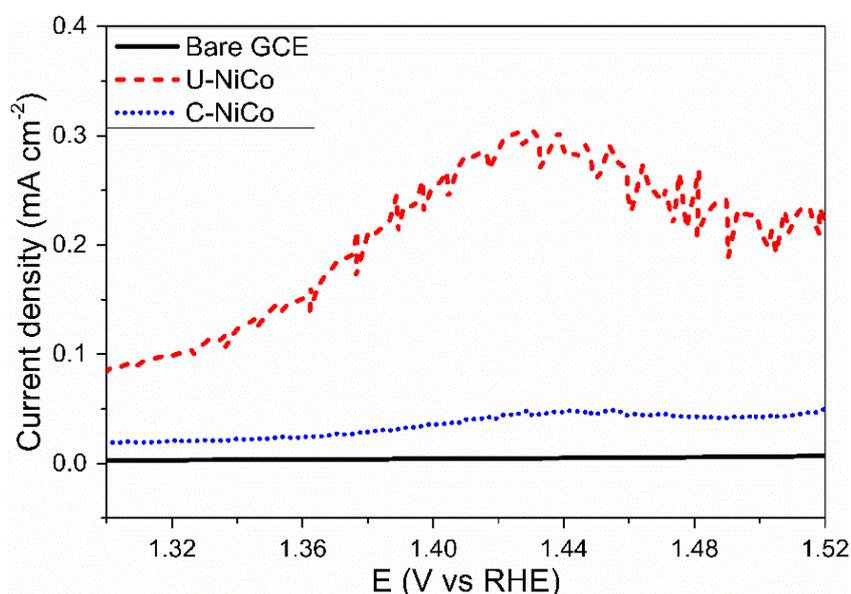

Figure 5.43. Polarization curves (in 1.30-1.52 V range) of bare GCE, U- and C-NiCo microspheres in 0.1 M KOH at a scan rate of 5 mV s^{-1}

ECSA was also estimated for the U- and C-NiCo microspheres by determining C_{dl} values (Figure 5.44). For U-NiCo, C_{dl} and ECSA were determined as 0.185 mF and 3.08 cm^2 , respectively. On the other hand, C-NiCo has C_{dl} value of 0.095 mF and ECSA of 1.58 cm^2 . Furthermore, RF values for U-NiCo and C-NiCo were determined to be 44 and 22.6, respectively. Higher C_{dl} , ECSA and RF values verify that U-NiCo possess larger number of active sites, and thus exhibit better electrocatalytic performance towards water oxidation reaction. At overpotential of 518 mV, mass activities and specific activities of both $\text{NiCo}_2\text{O}_4\text{-NiO}$ microspheres were calculated as 125 A g^{-1} and $1.14 \text{ mA cm}^{-2}_{\text{ECSA}}$ for U-NiCo while they were found to be 72.5 A g^{-1} and $1.28 \text{ mA cm}^{-2}_{\text{ECSA}}$ for C-NiCo, respectively. Higher mass and specific activities further confirm higher electrocatalytic activity of U-NiCo compared to C-NiCo. Furthermore, both U-NiO and C-NiO have significantly higher

mass activity and specific activity than those of monometallic Co_3O_4 (64.8 A g^{-1} , $0.93 \text{ mA cm}^{-2}_{\text{ECSA}}$) and NiO (61.6 A g^{-1} , $0.80 \text{ mA cm}^{-2}_{\text{ECSA}}$). All mass and specific activity calculated in this study are summarized in Table 5.4.

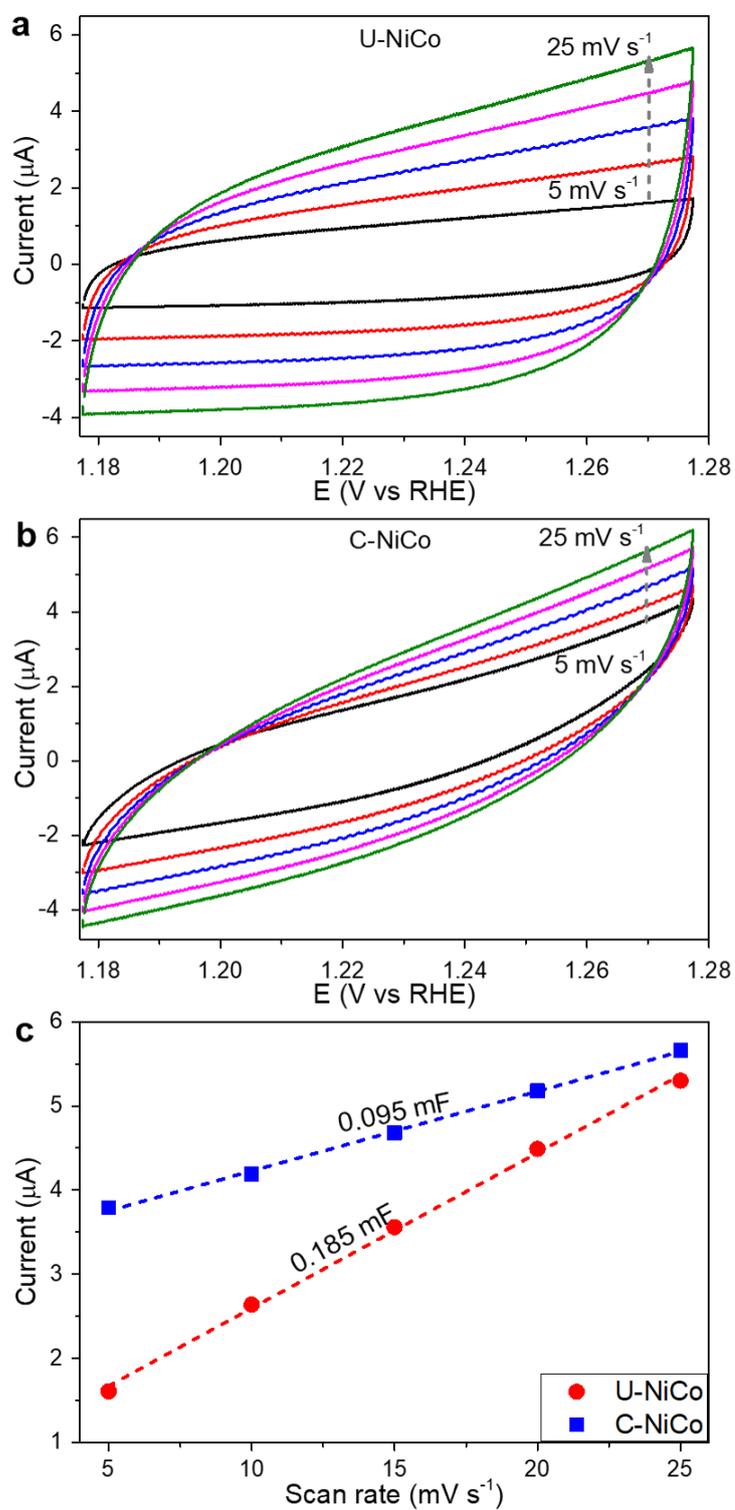

Figure 5.44. CVs of (a) U-NiCo, (b) C-NiCo microspheres measured at different scan rates from 5 to 25 mV s^{-1} and (c) Plot of current density at 1.27 V (vs RHE) vs scan rate of $\text{NiCo}_2\text{O}_4\text{-NiO}$ microspheres

Table 5.4 Summary of water oxidation properties of NiCo₂O₄-NiO microspheres

	Mass activity (A g ⁻¹) at $\eta=518$ mV	Specific activity (mA cm ⁻² _{ECSA})	C _{dl} (mF)	ECSA (cm ²)	RF
U-NiCo ₂ O ₄ -NiO	125	1.14	0.185	3.08	44
C-NiCo ₂ O ₄ -NiO	72.5	1.28	0.095	1.58	22.6
NiO	61.6	0.8	0.129	2.15	30.7
Co ₃ O ₄	64.8	0.93	0.078	1.95	27.8

The kinetics of the prepared catalysts in water oxidation reaction were further examined by EIS at various overpotentials. Nyquist plots of both U-NiCo and C-NiCo exhibited semicircles fitted to equivalent circuit of CPE, which is composed of R_u, constant-phase element and R_p (R_{ct}) (Figure 5.45). Diameter of the semicircles, which are associated with R_{ct}, decrease with the increasing overpotential. Lower charge transfer resistance indicates improved electrical conductivity resulting an increase in charge transfer during OER. The results reveal that U-NiCo has smaller R_{ct} (13.2 Ω) than the one of C-NiCo (18.5 Ω) at same applied potential (i.e. 640 mV vs Ag/AgCl), suggesting better conductivity and thus catalytic activity of U-NiCo.

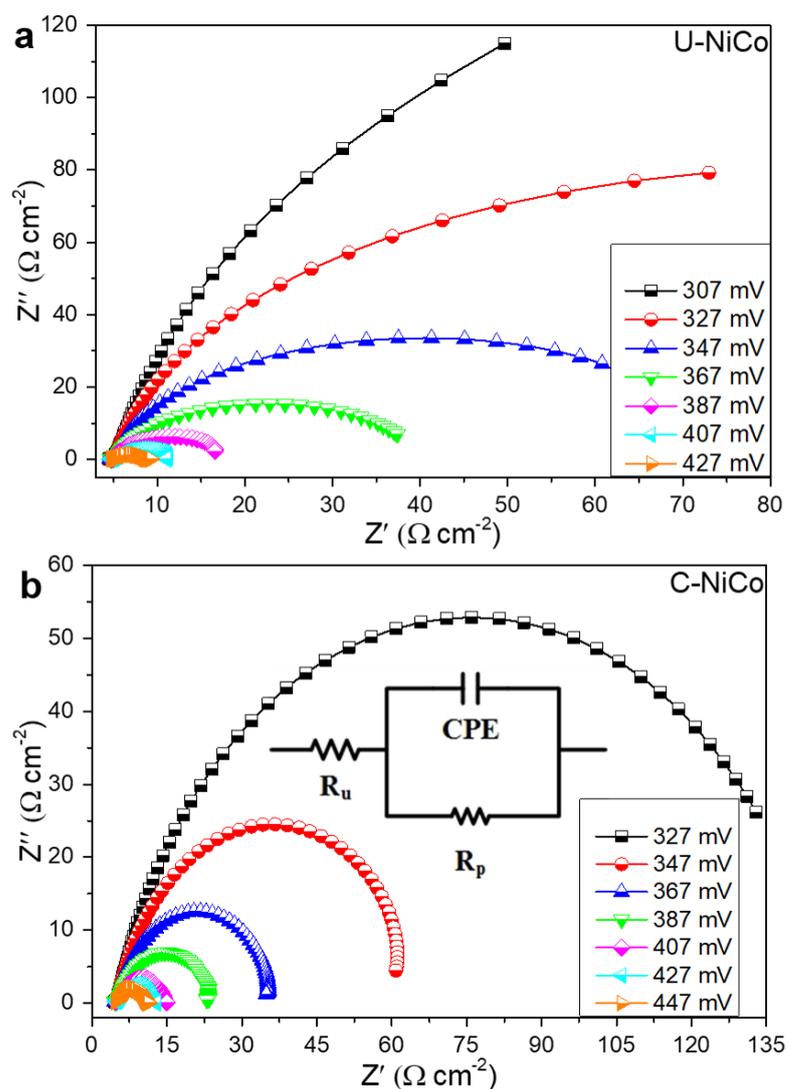

Figure 5.45. Nyquist plots of (a) U-NiCo and (b) C-NiCo microspheres at various overpotentials (inset shows the equivalent circuit diagram)

The durability of an electrocatalyst is a significant factor affecting its practical applications. Therefore, the stability of GCEs modified with $\text{NiCo}_2\text{O}_4\text{-NiO}$ nanomaterials were tested employing constant potential electrolysis in 0.1 M KOH solution. Overpotentials of 365 mV and 400 mV were applied for 10800 s for U-NiCo and C-NiCo, respectively. Figures 5.46a and 5.47a show the polarization curves recorded before and after electrolysis. A slight shift to higher overpotential

value (430 mV to 455 mV) at current density of 10 mA cm^{-2} was noted for C-NiCo while no noticeable change was recorded for U-NiCo. In addition, onset potentials of both U-NiCo and C-NiCo remained unchanged after 3 h of electrolysis, indicating that $\text{NiCo}_2\text{O}_4/\text{NiO}$ microspheres exhibit good stability under alkaline conditions.

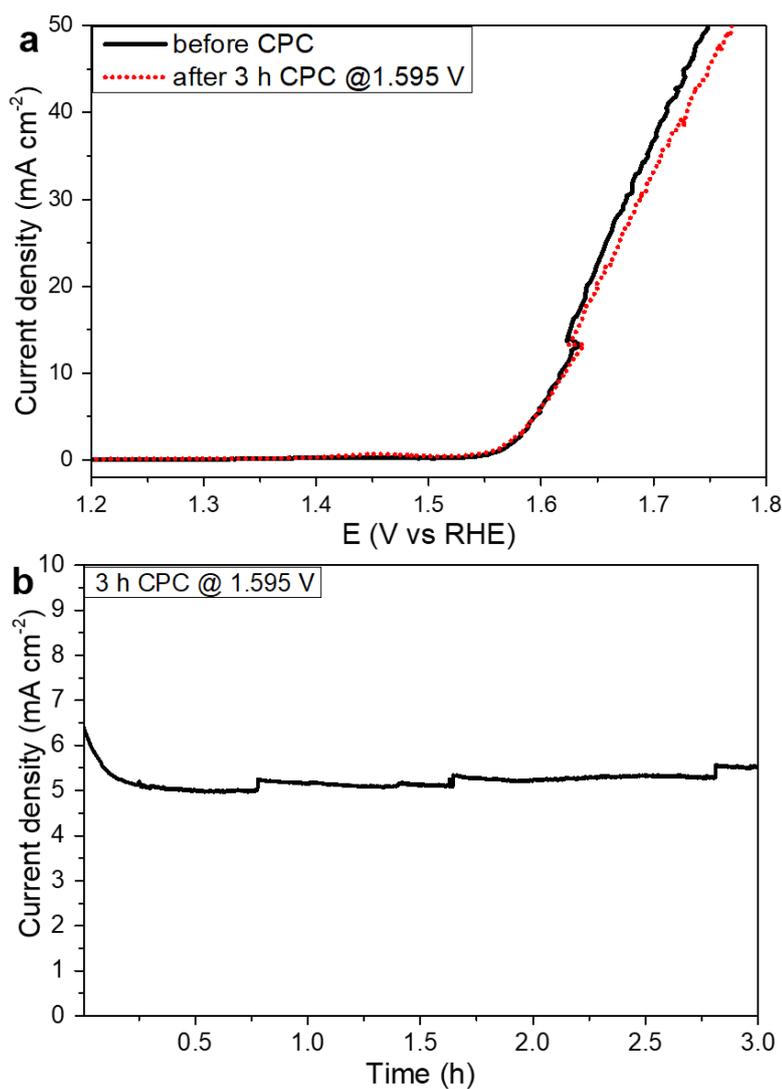

Figure 5.46. (a) Polarization curves of U-NiCo microspheres recorded before and after controlled potential electrolysis at overpotential corresponding to initial current density of 5 mA cm^{-2} and (b) The change in current density during electrolysis in 0.1 M KOH

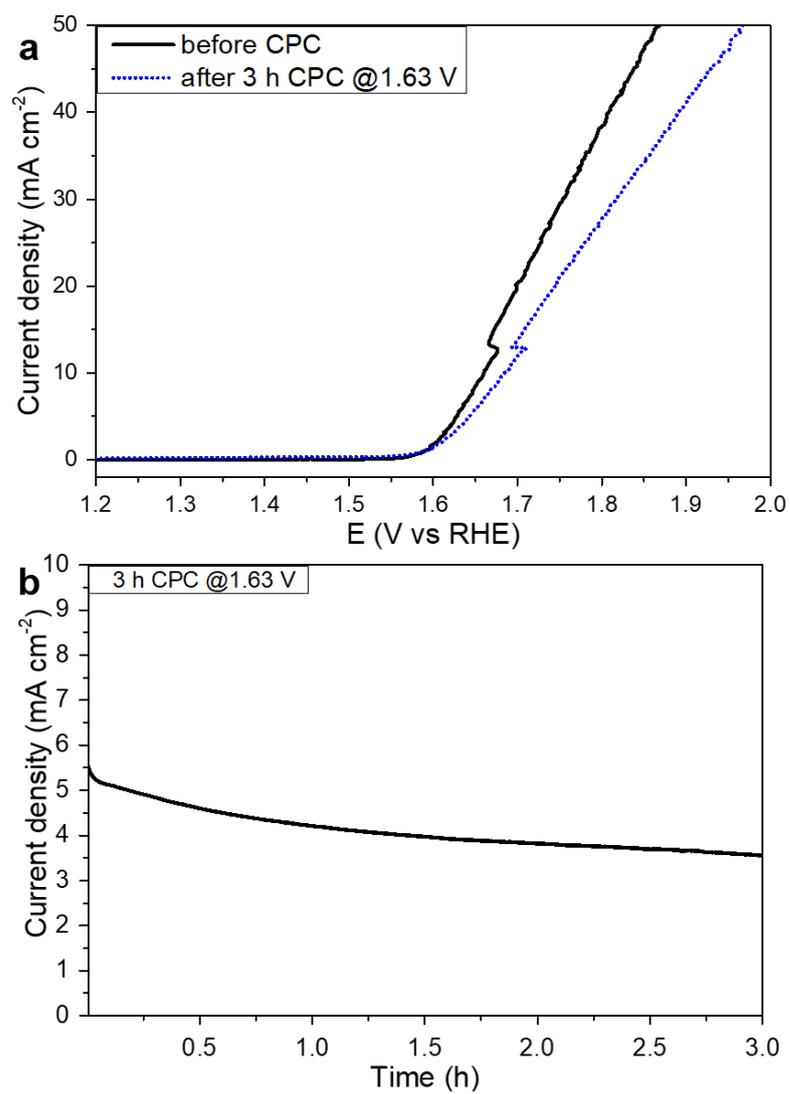

Figure 5.47. (a) Polarization curves of C-NiCo microspheres recorded before and after controlled potential electrolysis at overpotential corresponding to initial current density of 5 mA cm^{-2} and (b) The change in current density during electrolysis in 0.1 M KOH

5.2.5 Evaluation of electrocatalytic activities of the synthesized transition metal oxide nanomaterials for water oxidation reaction

Catalytic activity of the synthesized nanomaterials towards water oxidation reaction is governed by several chemical and morphological properties of the materials. Foremost, the large surface area, as evidenced by BET analyses (Table 5.5), enables more contact areas between electrode and electrolyte, facilitating the adsorption of the reactants and reaction intermediates. They are also valuable for enhanced electron transfer, and thus catalytic water oxidation.

In addition to surface area, presence of defect sites with low oxygen coordination in the material is also a significant parameter influencing the water oxidation activity of the catalyst. A number of studies reported that oxygen vacant sites promote H₂O adsorption onto catalyst surface. Consequently, it improves the reactivity of the catalyst.^{8,93-95} XPS O1s core-level spectra exhibit the presence of oxygen vacancies in all of the synthesized nanomaterials. Further inspection of the spectra revealed that relative peak areas are 51%, 46%, 61%, 63% and 58% for CuCr₂O₄ nanoparticles, FeMnO₃ nanowires, NiFe₂O₄-NiO nanoparticles, U-NiCo and C-NiCo microspheres, respectively. These slight differences in degree of oxygen deficiency is believed to contribute the variances in catalytic activity of the nanomaterials.

Table 5.5 Comparison of BET surface areas and degree of oxygen deficiencies of the synthesized nanomaterials

Catalyst	BET surface area (m ² g ⁻¹)	Degree of oxygen deficiency (%)
CuCr ₂ O ₄	10.63	51
FeMnO ₃	14.21	46
NiFe ₂ O ₄ -NiO	79.04	61
C-NiCo	13.40	58
U-NiCo	41.30	63

It has also been proposed that co-presence of two different metals in the structure can promote formation of multiple valence states of the cations.^{7,85,96} XPS spectra of the synthesized nanomaterials affirm the presence of metals with multiple oxidation states in each material. For instance, $\text{Fe}^{2+/3+}$ and $\text{Mn}^{3+/4+}$ ions coexist in nanowire structure. Furthermore, both U-NiCo and C-NiCo microspheres embody $\text{Ni}^{2+/3+}$ and $\text{Co}^{2+/3+}$ ions in their structure. The formation of such redox couples leads to higher electrical conductivity and enhanced surface adsorption properties, and thus improved electrocatalytic performances towards water oxidation reaction.

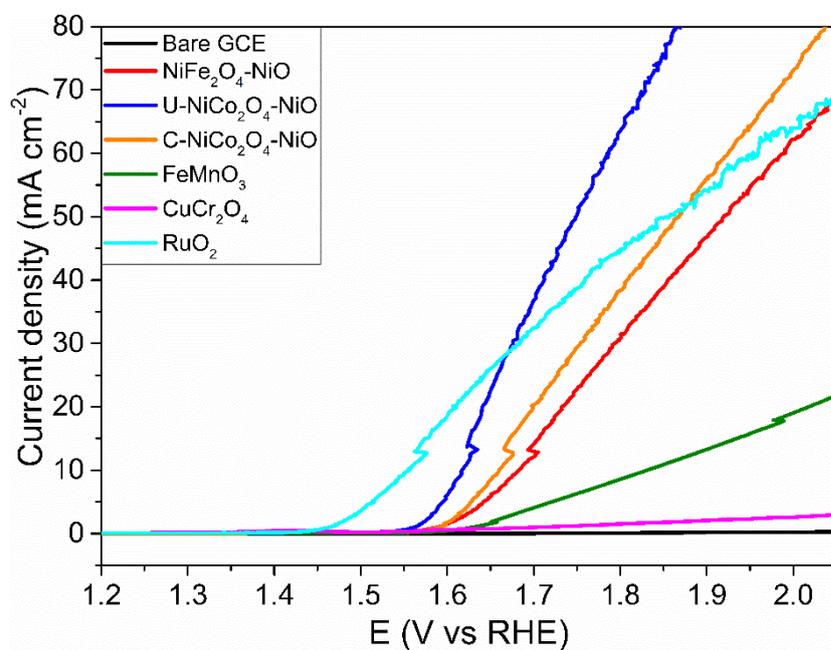

Figure 5.48. Polarization curves of bare GCE, CuCr_2O_4 nanoparticles, FeMnO_3 nanowires, $\text{NiFe}_2\text{O}_4\text{-NiO}$ nanoparticles, $\text{NiCo}_2\text{O}_4\text{-NiO}$ microspheres and RuO_2 in 0.1 M KOH solution at a scan rate of 5 mV s^{-1}

Table 5.6 Summary of water oxidation activity data of the nanomaterials synthesized in this study

	Electrode (cm ²)	Catalyst loading (mg cm ⁻²)	Onset (RHE)	η_{10} (mV)	η_{50} (mV)	Tafel slope (mV/dec)	ECSA (cm ²)	RF
U-NiCo	GC (0.07)	0.4	1.56	387	518	49	3.08	44
C-NiCo ₂	GC (0.07)	0.4	1.57	430	638	44	1.58	22.6
NiFe ₂ O ₄ -NiO	GC (0.07)	0.4	1.57	453	688	61	1.02	14.6
FeMnO ₃ *	FTO (0.5)	0.92	1.60	600	-	87	29.6	59.2
CuCr ₂ O ₄	GC (0.07)	0.4	2.07	1050	-	67	-	-
RuO ₂	GC (0.07)	0.4	1.45	326	622	60	20.5	292.8

* Surface area of electrode and catalyst loading is higher than the other studied electrodes.

Large surface area and presence of low oxygen coordination sites are significant parameters in the interpretation of catalyst activity. However, having larger surface area or higher degree of oxygen deficiency does not always result in more enhanced electrocatalytic activity. For instance, when relation of oxygen deficiency and catalytic activity of studied materials are compared, CuCr₂O₄ nanoparticles with relatively higher oxygen deficiency than FeMnO₃ nanowires have significantly lower activity in OER. On the other hand, comparison of BET surface areas reveal that CuCr₂O₄ has the lowest area among all synthesized materials. NiFe₂O₄-NiO nanoparticles are expected to have the highest catalytic activity for water oxidation reaction since they bear the largest surface area. In addition, having similar BET surface areas of 14.21 m² g⁻¹ and 13.40 m² g⁻¹, FeMnO₃ nanowires and C-NiCo microspheres should display similar performance, respectively. Nevertheless, U-NiCo microspheres exhibit the highest electrocatalytic activity with its lower BET surface area of 41.30 m² g⁻¹ compared to that of NiFe₂O₄-NiO nanoparticles (Figure 5.47). These comparisons suggest that oxygen deficiency and/or surface area can not be considered as only parameters affecting catalytic activity, and individual or combination of possible other factors such as chemical composition, electrochemically active surface area and conductivity can be the reason for observed activities. Therefore, determination of ECSA, which is directly related with the

number of sites acting as catalyst, is crucial to make more reliable assessment of catalyst performance. As summarized in Table 5.6, enhancement of the water oxidation activity is observed with increasing ECSA of the catalyst. FeMnO_3 nanowires exhibit lower electrocatalytic activity than the Ni-based ones even though it has the largest ECSA value. It is important to note that the large ECSA value is most likely due to the large surface area of FTO electrode and the higher amount of catalyst on the surface. In addition, RuO_2 has the largest ECSA value which correlate well with the observed water oxidation activity. Thus, our results clearly show that increase in the ECSA of the studied catalyst results in the increased activity as expected.

CHAPTER 6

CONCLUSIONS

The aim of this thesis was to design and prepare bimetallic oxide nanomaterials using earth abundant, first row transition metals to be used as catalysts in the electrochemical water oxidation reaction. Synthesized materials were characterized by a combination of analytical techniques including SEM, TEM, EDX, XRD, XPS, ICP-OES and BET. Then, their activities were studied for water oxidation reaction by utilizing electrochemical techniques.

In summary, a series of bimetallic transition metal oxide nanomaterials with various morphologies were synthesized by facile, solution-phase procedures using different structure directing agents. Specifically, CuCr_2O_4 nanoparticles were obtained via sol-gel route in which citric acid was used as surfactant. FeMnO_3 , $\text{NiFe}_2\text{O}_4\text{-NiO}$ and $\text{NiCo}_2\text{O}_4\text{-NiO}$ nanomaterials were obtained by utilizing hydrothermal process. NTA was used as structure directing agent in the synthesis of FeMnO_3 , while $\text{NiFe}_2\text{O}_4\text{-NiO}$ and $\text{NiCo}_2\text{O}_4\text{-NiO}$ were synthesized with the use of urea. In addition to urea, CTAC was also used as structure directing agent in the synthesis of $\text{NiCo}_2\text{O}_4\text{-NiO}$.

Electron microscopy studies revealed that synthesized materials comprise of assembled individual nanoparticles. CuCr_2O_4 nanoparticles are of quasi-spherical morphology with average size of 28 nm. FeMnO_3 nanowires are formed by the assembly of approximately 70 nm particles. $\text{NiFe}_2\text{O}_4\text{-NiO}$ nanoparticles resulted from the accumulation of approximately 30 nm spherical like particles. Moreover, by using two different surfactants, namely urea and CTAC, $\text{NiCo}_2\text{O}_4\text{-NiO}$ nanomaterials are obtained as microspheres. Urea-stabilized $\text{NiCo}_2\text{O}_4\text{-NiO}$ has urchin-like morphology assembled by nanowires, and CTAC stabilization lead to the formation of microspheres with nanoplate assembly. In addition, both wires and plates are composed of individual nanoparticles.

The electrocatalytic performances of synthesized nanomaterials in water oxidation reaction were evaluated in alkaline medium (0.1 M KOH) (Figure 5.48). The results revealed that CuCr_2O_4 nanoparticles exhibit almost no activity towards water oxidation reaction with very high onset (2.07 V vs RHE) and overpotentials ($\eta_{10} = 1.05$ V). FeMnO_3 nanowires had onset potential of 1.60 V (vs RHE) with an overpotential of 600 mV at current density of 10 mA cm^{-2} and Tafel slope of 87 mV dec^{-1} . $\text{NiFe}_2\text{O}_4\text{-NiO}$ nanoparticles demonstrate slightly better activity with an onset potential of 1.57 V (vs RHE), and overpotential required to generate current density of 10 mA cm^{-2} was 453 mV. In addition, Tafel slope was determined as 61 mV dec^{-1} indicating faster water oxidation kinetics. $\text{NiCo}_2\text{O}_4\text{-NiO}$ microspheres, on the other hand, present more enhanced activity. Onset potentials observed for U-NiCo and C-NiCo were 1.56 V (vs RHE) and 1.57 V (vs RHE), respectively. Additionally, U-NiCo and C-NiCo can promote 10 mA cm^{-2} current density at lower overpotentials of 387 mV and 430 mV, respectively. Tafel slope of U-NiCo was determined as 49 mV dec^{-1} while for C-NiCo it was found as 44 mV dec^{-1} . These results suggest that $\text{NiCo}_2\text{O}_4\text{-NiO}$ microspheres display the best water oxidation activity among the nanomaterials synthesized in this study (Table 5.6).

The durability of the prepared catalysts was also studied by long term controlled potential coulometry. After 3 h of electrolysis, a slight increase in onset potential was noted for FeMnO_3 nanowires. On the other hand, this value remained constant for $\text{NiFe}_2\text{O}_4\text{-NiO}$ nanoparticles (after 5 h of electrolysis) and $\text{NiCo}_2\text{O}_4\text{-NiO}$ microspheres (after 3 h of electrolysis) indicating very good stability of these materials during water oxidation reaction.

As a result, bimetallic transition metal oxide nanomaterials, namely CuCr_2O_4 nanoparticles, FeMnO_3 nanowires, $\text{NiFe}_2\text{O}_4\text{-NiO}$ nanoparticles and $\text{NiCo}_2\text{O}_4\text{-NiO}$ hierarchical microspheres with interesting morphologies were synthesized and their electrochemical activities for water oxidation reaction were investigated. The overall water oxidation activity of the synthesized materials was observed to be comparable or superior to some of the water oxidation electrocatalysts having similar structures. These new materials with their exciting morphologies, easy synthesis from earth

abundant elements, stability and ability to deliver high current densities are practically very useful and effective catalysts for water oxidation reaction.

For future work, water oxidation reaction mechanism, the active sites in each catalyst as well as the rate determining step can be investigated in detail with the aid of computational analysis. Moreover, their potential utility in other applications such as supercapacitors, metal-air batteries, hydrogen evolution reaction (HER), oxygen reduction reaction (ORR) or various other catalysis applications such as dehydrogenation, hydrogen peroxide reduction, CO oxidation.

A. N₂ adsorption – desorption isotherms of synthesized materials

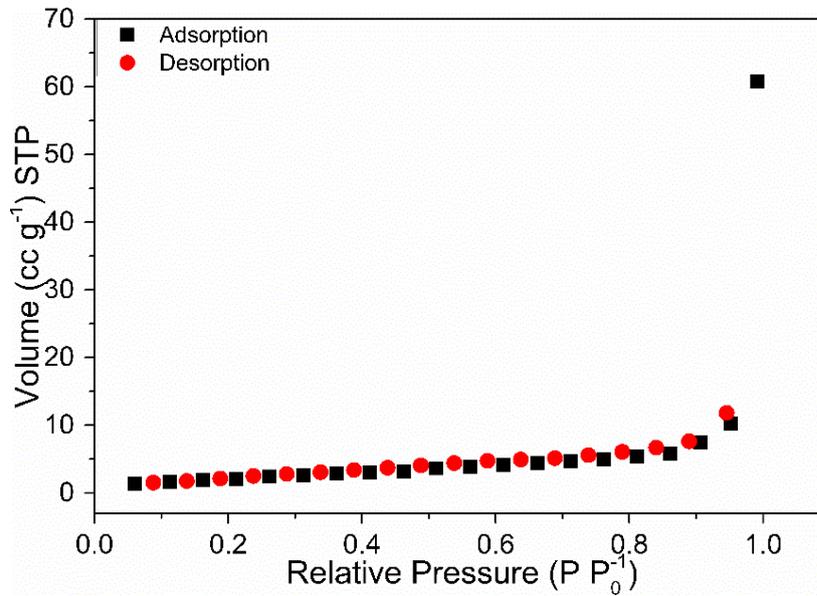

Figure A.1. N₂ adsorption – desorption isotherm of CuCr₂O₄ nanoparticles

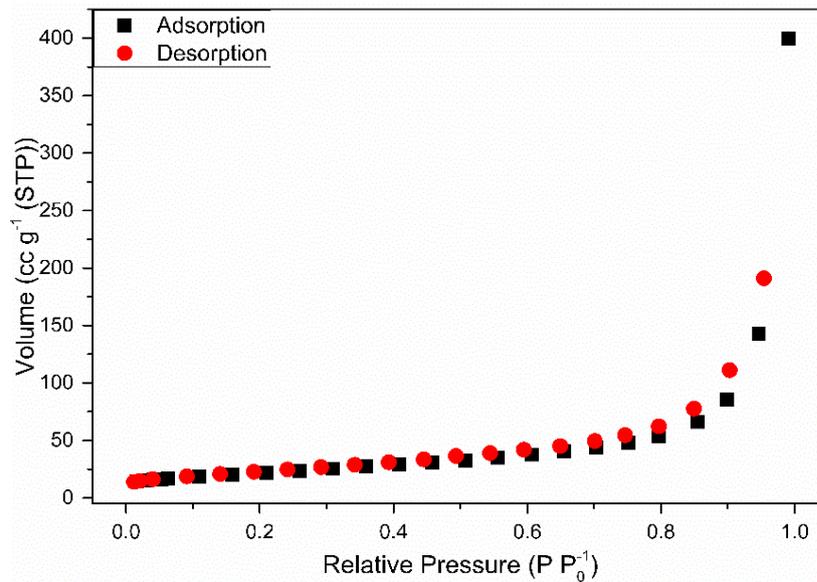

Figure A.2. N₂ adsorption – desorption isotherm of NiFe₂O₄-NiO nanoparticles

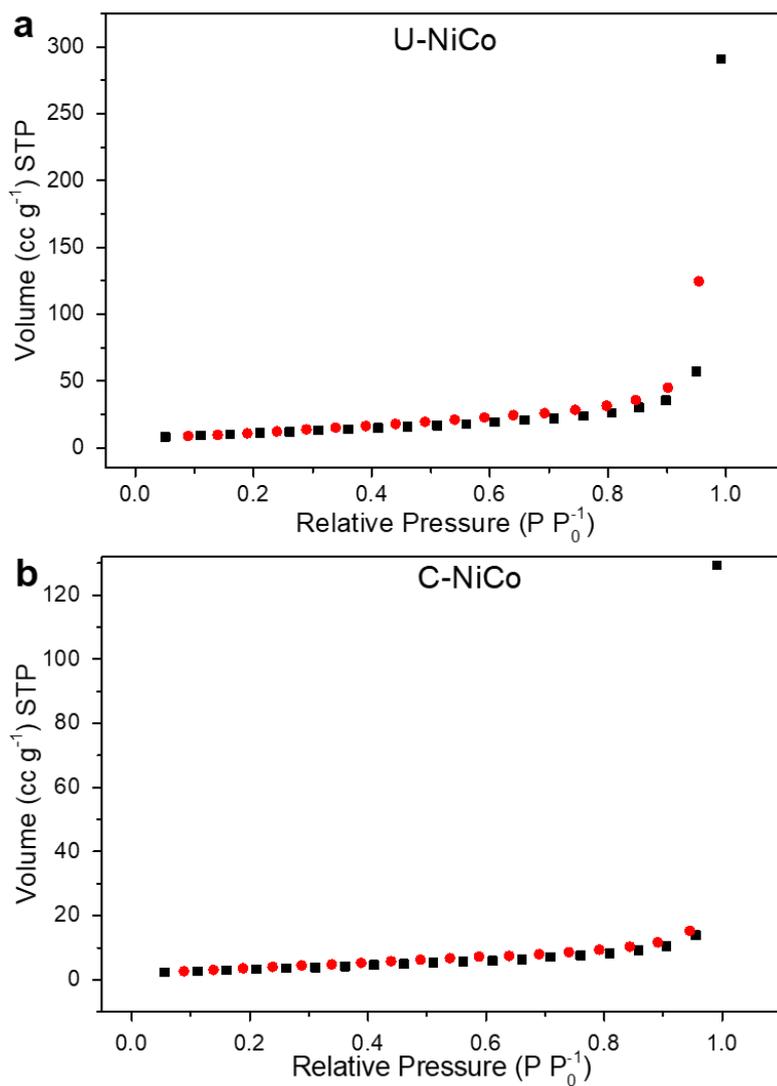

Figure A.3. N_2 adsorption – desorption isotherms of (a) U-NiCo and (b) C-NiCo microspheres

B. Electrochemical Activity of CuCr₂O₄ Nanoparticles for Water Oxidation in Sodium Borate Buffer Solution

Electrode Preparation

Electrodes modified with CuCr₂O₄ Nanoparticles were prepared by a method reported by Kuo et al.⁵⁴ Briefly, 4.0 mg of catalyst was dispersed in 1.0 mL ethanol and 1.0 mL deionized water mixture. After ultrasonication, Nafion was added and sonicated for 20 min. 7.5 μ L of solution was dropped onto GC electrodes and dried in oven (90 °C). The effect of carbon materials (Printex L6 (PL6), Super C65, multiwalled carbon nanotube (MWCNT)) addition into catalyst solution as well as effect of carbon and Nafion[®] amount on onset potential and current density were also investigated and the electrodes were prepared by the same recipe.

Electrochemical Measurements

All electrochemical measurements were performed at room temperature with Gamry PCI4/300 potentiostat-galvanostat. GC electrode modified with CuCr₂O₄ Nanoparticles were used as working electrode in a standard three-electrode configuration with Pt wire as cathode and Ag/AgCl as reference electrode. LSV of GC electrode modified with CuCr₂O₄ Nanoparticles were obtained by scanning the potential from 0 – 1.2 V (vs Ag/AgCl) with a scan rate of 10 mV s⁻¹ in 0.1 M sodium borate buffer (pH: 9.2).

Effect of Nafion[®] amount on onset potential

Effect of Nafion[®] amount on onset potential was investigated in order to determine the optimum value. Figure B.1 demonstrates the polarization curves obtained from electrodes prepared by different amount of Nafion[®] (i.e. 9.5 μ L, 19.0 μ L and 38.0 μ L) to the catalyst mixture. Comparison of the curves revealed that addition of 38.0 μ L of Nafion[®] resulted in higher onset potential and lower current density values. The most likely reason for this observation is that high amount of polymer solution may have blocked the electrode surface, and thus limited the electron transfer.

Among the other two electrodes, the electrode with 9.5 μL of Nafion[®] exhibited slightly higher onset potential and lower current density compared to the one with 19.0 μL Nafion[®]. Therefore, 19.0 μL Nafion[®] was used in the preparation of electrodes in the following electrochemical measurements.

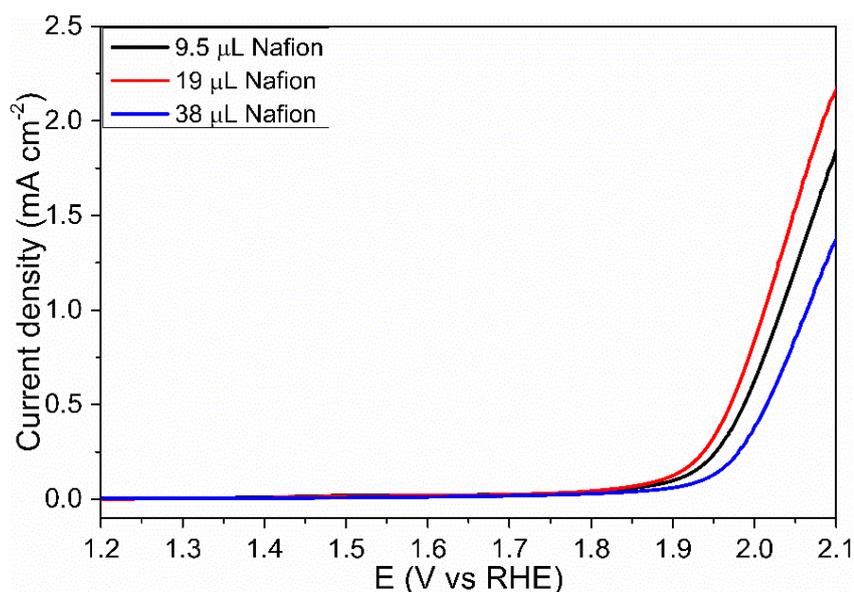

Figure B.1. Polarization curves of CuCr_2O_4 nanoparticles with different amount of Nafion[®] in 0.1 M KOH at a scan rate of 5 mV s^{-1}

Effect of Carbon Materials on onset potential

Previously reported studies have shown that adding carbon to the solution from which the electrodes were prepared have increased the current passing the electrode, and thus prepared electrodes by mixing carbon and catalyst in deionized water/ethanol mixture.^{5,54,97-99} Therefore, in this study too, the effect of carbon presence was investigated.

Figure B.2a shows the polarization curves of CuCr_2O_4 Nanoparticles along with the one mixed with carbon (PL6) and bare GCE. Modified electrodes exhibited lower onset potentials compare to bare GC electrode as expected. No significant change

was observed for onset potentials upon addition of PL6 while a slight increase in current density was noted. However, adding carbon to the catalyst mixture appears to have no significant effect on water oxidation activity. The effect of only carbon on onset potential was also investigated (Figure B.2b). Carbon material has no effect on neither onset potential nor current density, as expected. As a result, the decrease in onset potential in CuCr_2O_4 -GC electrodes are attributed to presence of the nanoparticles.

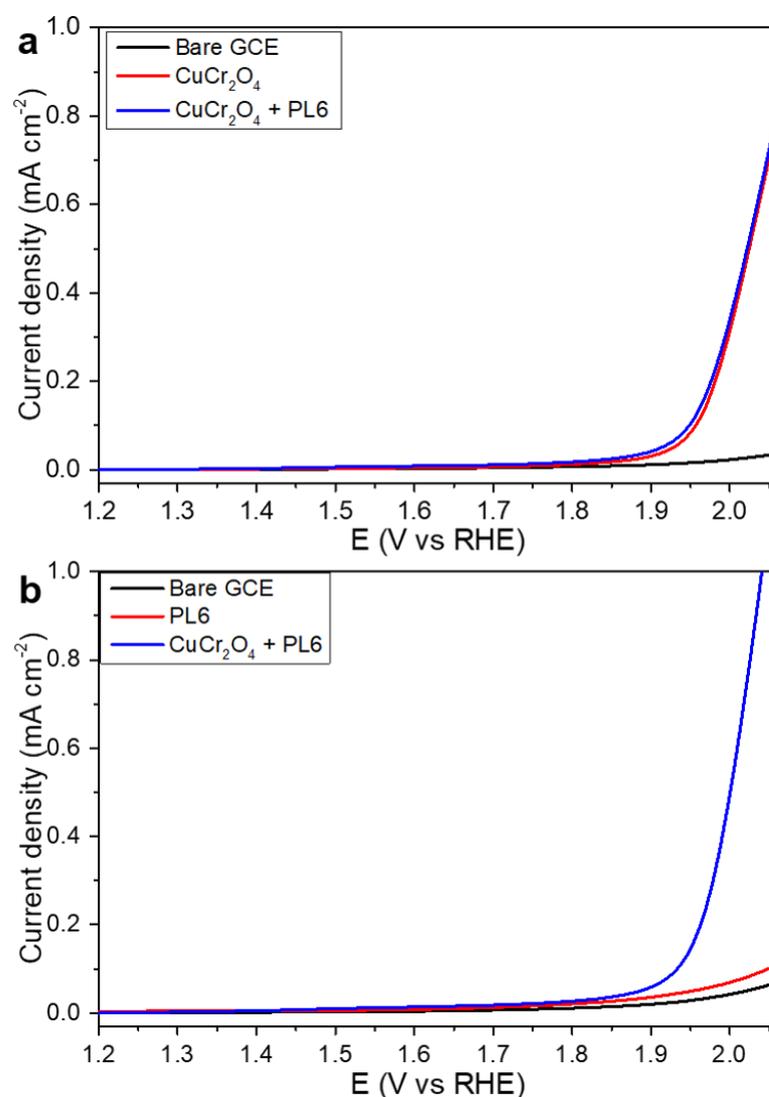

Figure B.2. Polarization curves of bare GCE, CuCr_2O_4 nanoparticles and CuCr_2O_4 nanoparticles mixed with PL6 in 0.1 M KOH at a scan rate of 5 mV s^{-1}

Figure B.3a shows the polarization curves of electrodes prepared by different carbon loading (w/w % relative to amount of catalyst). Very slight differences in onset potentials were recorded with different carbon loadings. The most significant change in both onset potential and current density was noted for the electrode with 10% carbon. Therefore, 10% carbon loading used for the following measurements. Electrodes were also prepared by using Super C65 carbon instead of PL6. The resulting polarization curves are given in Figure B.3b. Inspection of the curves reveal that the type of carbon material used has no significant effect neither on onset potential or current density.

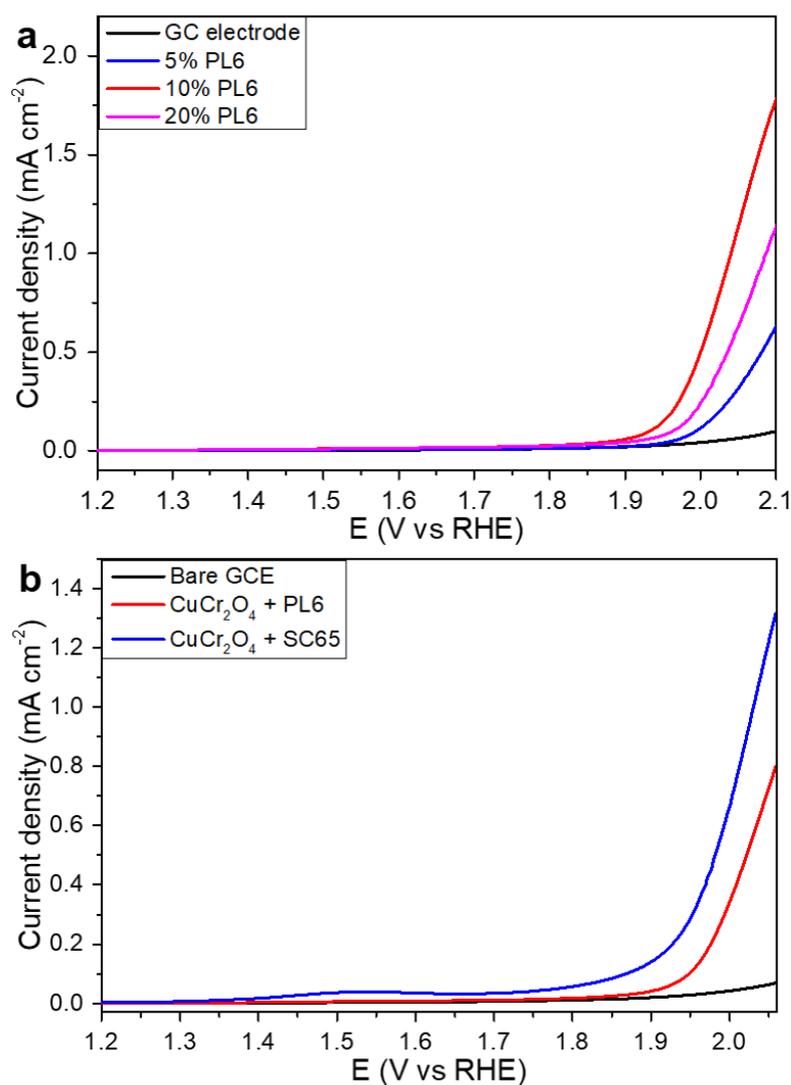

Figure B.3. Polarization curves of CuCr₂O₄ nanoparticles obtained with (a) different carbon loadings and (b) different carbon materials in 0.1 M KOH at a scan rate of 5 mV s⁻¹

During these studies it was observed that modified GC electrodes were not as stable and Nanoparticles were detaching from the electrode surface. Therefore, GC electrodes were modified by the method described in Section 4.4.1. In addition to previous studies, the effect of MWCNT on onset potential was also tested. Polarization curves of CuCr₂O₄ nanoparticles along with the one mixed with carbon

(PL6 and MWCNT) and bare GC electrode are given in Figure B.4. As observed from the curves, addition of carbon to the catalyst solution has no effect on onset potential and current density, and thus electrocatalytic activity of the Nanoparticles toward water oxidation reaction. Moreover, maximum current density value the catalyst could generate was 1.2 mA cm^{-2} with the use of sodium borate solution, as explained in Section 3.1.2. Therefore, 0.1 M KOH solution was used in the investigation of electrochemical activities of nanomaterials for water oxidation reaction. The data obtained for CuCr_2O_4 Nanoparticles in sodium borate solution is summarized in Table B1.

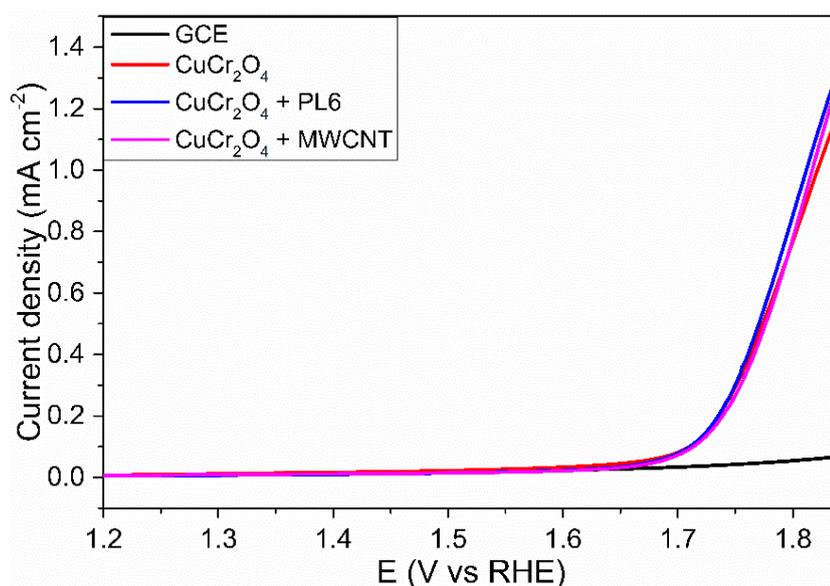

Figure B.4. Polarization curves of CuCr_2O_4 nanoparticles and CuCr_2O_4 nanoparticles mixed with PL6 and MWCNT in 0.1 M KOH at a scan rate of 5 mV s^{-1}

Table B.1 Summary of the data obtained for CuCr_2O_4 nanoparticles in sodium borate buffer solution

Electrode		Onset (V) (RHE)	Max j (mA cm⁻²) at η:830 mV
Nafion[®]	9.5 μL	1.9	1.35
	19.0 μL	1.89	1.68
	38.0 μL	1.96	0.95
CuCr_2O_4		1.95	0.776
CuCr_2O_4 + PL6	5 %	1.98	0.37
	10 %	1.94	1.27
	20 %	1.96	0.72
CuCr_2O_4 + SC65	10 %	1.9	1.32
CuCr_2O_4 + MWCNT	10 %	1.92	1.3

C. EIS fitting data of the synthesized nanomaterials

Table C.1 EIS data of FeMnO₃ nanowires

Potential (mV vs Ag wire)	R _u (Ω cm ⁻²)	R _p (Ω cm ⁻²)	Y ₀
680	28.4	380	388.5 x 10 ⁻⁶
700	29.8	150.7	386.3 x 10 ⁻⁶
720	29.0	70.7	408.2 x 10 ⁻⁶
740	28.4	44.8	454.2 x 10 ⁻⁶
760	28.0	32.7	483.4 x 10 ⁻⁶
780	27.8	26.8	486.4 x 10 ⁻⁶

Table C.2 EIS data of NiFe₂O₄-NiO nanoparticles

Potential (mV vs Ag/AgCl)	R _u (Ω cm ⁻²)	R _p (Ω cm ⁻²)	Y ₀
560	8.8	949.7	3.0 x 10 ⁻³
580	9.4	251.4	2.8 x 10 ⁻³
600	8.4	122.6	2.7 x 10 ⁻³
620	7.2	58.1	2.6 x 10 ⁻³
640	7.2	33.0	2.4 x 10 ⁻³
660	5.5	22.5	2.8 x 10 ⁻³
680	5.0	13.4	2.2 x 10 ⁻³

Table C.3 EIS data of C-NiCo microspheres

Potential (mV vs Ag/AgCl)	R_u ($\Omega \text{ cm}^{-2}$)	R_p ($\Omega \text{ cm}^{-2}$)	Y_0
580	5.0	141.8	2.5×10^{-3}
600	5.0	61.1	2.3×10^{-3}
620	5.0	32.3	2.3×10^{-3}
640	5.2	18.8	2.3×10^{-3}
