THE EFFECT OF EXPERIMENTAL CONDITIONS ON NATURAL GAS HYDRATE FORMATION

A THESIS SUBMITTED TO
THE GRADUATE SCHOOL OF NATURAL AND APPLIED SCIENCES
OF
MIDDLE EAST TECHNICAL UNIVERSITY

BY

SOTIRIOS LONGINOS

IN PARTIAL FULFILLMENT OF THE REQUIREMENTS FOR
THE DEGREE OF DOCTOR IN PHILOSOPHY IN
PETROLEUM AND NATURAL GAS ENGINEERING

JULY 2020
THE EFFECT OF EXPERIMENTAL CONDITIONS ON NATURAL GAS HYDRATE FORMATION

submitted by SOTIRIOS LONGINOS in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Petroleum and Natural Gas Engineering Department, Middle East Technical University by,

Prof. Dr. Halil Kalpçilar
Dean, Graduate School of Natural and Applied Sciences

Assoc. Prof. Dr. Çağlar Sınayuç
Head of Department, Petroleum and Natural Gas Engineering

Prof. Dr. Mahmut Parlaktuna
Supervisor, Petroleum and Natural Gas Eng. Dept., METU

Asst. Prof. Dr. İnci Ayrancı Tansık
Co-Supervisor, Chemical Eng. Dept., METU

I hereby declare that all information in this document has been obtained and presented in accordance with academic rules and ethical conduct. I also declare that, as required by these rules and conduct, I have fully cited and referenced all material and results that are not original to this work.

Name, Last name:  Sotirios Longinos

Signature:
Natural gas hydrates (NGH) are proposed as gas storage and transportation media owing to their high gas content and long-term stability of hydrate crystal structure at common refrigeration temperatures and atmospheric pressure. Technically feasible, cost efficient hydrate production is one of the crucial items of the whole chain of storage and transportation of gas by means of NGH technology. This study investigated the effects of types of impellers and baffles, and the use of promoters on natural gas hydrate formation.

Up-pumping pitched blade turbine (PBTU) and Rushton turbine (RT) were the two types of impellers tested. The reactor was equipped with different designs of baffles: full, half and surface baffles, or no baffles. In total 48 experiments were completed with different impeller – baffle combinations. Single (PBTU or RT), dual (PBTU/PBTU or RT/RT) and dual-mixed (PBTU/RT or RT/PBTU) use of impellers with full (FB), half (HB), surface (SB) and no baffle (NB) combinations formed two sets of 24 experiments. The first set was completed with the use of pure methane as hydrate forming gas and in the second set methane – propane mixture (95% - 5%) was used.
Experimental data was analyzed in terms of induction time, hydrate formation rate, overall power consumption, hydrate productivity and conversion of water to hydrate. In addition, split fraction of methane and propane in free gas and solid hydrate during hydrate formation from mixture gas is determined. The reactor was operated in batch mode in all the experiments.

Single impeller experiments with methane showed that Rushton turbine has better performance than up-pumping pitched blade turbine, for all kind of baffles. Use of dual impellers, either the same type or mixed, produced similar results of single impeller. The initial hydrate formation rate is generally higher with the use of Rushton turbine, but the decline rate of hydrate formation was also high compared to up-pumping pitched blade turbine (PBTU). The higher amount of hydrate formed at the gas-water interface initially restricts the mass transfer between gas and water phases and results in a higher decline in the formation rate of hydrate. The other fact causing the decline in hydrate formation rate is the exothermic nature of hydrate formation. Hydrate formation process by gas mixtures become more complex because of different partition of gas components in free gas and solid hydrate phases. Propane is consumed more if hydrate is formed from a gas mixture of methane – propane. This fact brings another complexity of varying hydrate equilibrium curve during hydrate formation. As propane is consumed, hydrate equilibrium pressure gets higher for the given process temperature. Aqueous solutions of amino acids tested in this study showed shorter induction time and generally higher hydrate formation rates compared to distilled water. This indicates a potential of finding hydrate promoters among these amino acids.

**Keywords:** natural gas hydrates, rate of hydrate formation, induction time, amino acids.
ÖZ

DENEYSEL KOŞULLARIN DOĞAL GAZ HİDRAT OLUŞUMUNA ETKİLERİ

Yardımcı Tez Yöneticisi: Dr. Öğretim Üyesi İnci Ayrancı Tansık

Temmuz 2020, 260 sayfa

Doğal gaz hidratları (NGH), yapılarındaki yüksek gaz içeriği ve hidrat kristal yapısının günümüz derin dondurucu teknolojisinde kullanılan sıcaklık ve atmosferik basınç şartlarındaki uzun süreli kararlı yapı nedeniyle doğal gazın depolanması ve taşınması için önerilmektedir. Teknik olarak uygulanabilir ve ekonomik bir hidrat üretim süreci, NGH teknolojisi ile gaz depolama ve taşıma zincirinin önemli öğelerinden birisidir. Bu çalışmada karıştırıcı ve engel türleri ile kimiyasal hızlandırıcıların doğal gaz hidrat oluşumu üzerindeki etkileri araştırılmıştır.

Yukarı pompalayan eğimli büyükli karıştırıcı (PBTU) ve Rushton türbini (RT) çalışmada kullanılan iki karıştırıcı türüdür. Deneyler sırasında reaktör tam (FB), yarım (HB) veya yüzey (SB) engellerinden biriyle donatılmış ya da engel kullanılmamıştır. Çalışmada farklı karıştırıcı – engel kombinasyonları ile 48 adet deney gerçekleştirilmiştir. Tek karıştırıcı (PBTU veya RT), aynı türden çift karıştırıcı (PBTU/PBTU veya RT/RT) ve son olarak farklı türden çift karıştırıcı (PBTU/RT veya RT/PBTU) kullanılan deneylerde tam (FB), yarım (HB), yüzey (SB) veya engelsiz (NB) engel türleriyle iki adet 24 deneylik grup oluşturulmuştur. İlk grupta hidrat oluşturan gaz saf metan iken ikinci grupta % 95 metan - % 5 propandan oluşan gaz karışımı hidrat oluşumu için kullanılmıştır.

vii

Saf metan kullanılarak gerçekleştirilen tek karıştırıcılı deney sonuçları, tüm engeller için, Rushton türbin tipi karıştırıcının yukarı pompalayan eğimli biçaklı karıştırıcıdan daha iyi performansa sahip olduğunu göstermiştir. Aynı türden veya farklı türden ikili karıştırıcılarla gerçekleştirilen deneylerde de benzer sonuçlar elde edilmiştir. Rushton türbinle yapılan deneylerde ilk an hidrat oluşum hızı, genel olarak, yukarı pompalayan eğimli biçaklı karıştırıcı deneylerin ilk an hidrat oluşum hızlarından yüksek olması rağmen hidrat oluşum hızının değişim hızı da yüksektir. Yüksek ilk an hızıyla gaz – su arayüzünde oluşturulan yüksek miktardaki hidrat fazlar arası kütle transferini kısıtlamakta ve ilerleyen zamanla hidrat oluşum hızını düşürmektedir. Hidrat oluşum hızının düşmesinin bir diğer nedeni de hidrat oluşumunun ekzotermik bir süreç olması rağmen hidrat oluşum hızının değişim hızı da yüksektir. Yüksek ilk an hızıyla gaz – su arayüzünde oluşturulan yüksek miktardaki hidrat fazlar arası kütle transferini kısıtlamakta ve ilerleyen zamanla hidrat oluşum hızını düşürmektedir. Hidrat oluşum hızının düşmesinin bir diğer nedeni de hidrat oluşumunun ekzotermik bir süreç olması rağmen hidrat oluşum hızının değişim hızı da yüksektir. To My Father Nikolao, My Mother Anastasia & My Sister Dionisia-Dimitra
ACKNOWLEDGEMENTS

I would like to acknowledge and express my sincere gratitude to my thesis advisor Prof. Dr. Mahmut Parlaktuna for his supervision and support throughout the study. Dr. Parlaktuna was not just a supervisor but also a mentor with his actions in my personal life. I would also like to thank Mrs. Nevruz Parlaktuna for her behavior during my six years in Ankara. Many thanks to my thesis committee members for their contributions.

I would also like to thank one person that was very close and helped me during the process of my thesis who is Özgür Çoban, General Manager of Hydecon. Moreover, I would like to say a big thank to technician Murat Çalışkan for his assistance during my experimental process. I also appreciate the assistance of Naci Doğru during my experiments. One special thanks to Dr Sevtaç Bülbül (Miss Angel) for his kindness to help me any time I asked her assistance.

During my six years in Ankara I made a lot, very good and important friends. One thank for them from the depth of my heart is little but imposed. I would like to thank Emre (first roommate), Duygu, Deniz (yoldaş), Şükrü, Burak, İnanç, Gökhan (project mate), Fikret, Caner, Emre, Murat, Erdem, Serkhan, Behrang, Can, Hasan (lab mate), Kamila, Buğra, Elif, Ozan (Greek Muslim minority), Ayşegül, Fatma, Ayşegül,

I would also like to thank all the professors and instructors of petroleum and natural gas engineering department for their kindness to help me and solve any of my queries during my student life. Special thanks to Mr. Can Bakiler the most kind and gentle person that I met in Turkey. Important thanks to Dr. Uğur Murat Leloğlu, Dr. İsmail Durgut and Dr. Çağlar Sinayuçoğlu for their help and kindness during my stay. Last but not least, I would like to say special thanks to Professor Dr. Serhat Akın for his courses that I took during my study.
This study is financially supported by TUBITAK through the project 117M158. Most of the equipment of the experimental setup were purchased by the project budget. In addition, monthly fellowships from the project financially eased by stay in Ankara. Those financial supports are highly appreciated.

I also thank to the administration of the Petroleum Research Center of Middle East Technical University for the chromatographic analysis of gas mixtures. Laboratory technician Mr. Mutlu Uğurlu also deserves a special thank.

Above all, I would like to say a big thank and dedicate this thesis to my parents and the other half of my life, my beloved sister. These three persons are the foundation stone and the lighthouse of my life and without their love, support and encouragement this work would not be finished.

**NOMENCLATURE**

A  
Average cavity radius

A\(^0\)  
Cavity Diameter

AA  
Anti-agglomerate

ABS  
Acrylonitrile butadiene styrene

AFP  
Antifreeze protein

BOP  
Blowout preventers

C\(_{16}\)H\(_{31}\)NO  
N-dodecylpyrrolidone

C\(_{18}\)H\(_{33}\)NaO\(_2\)  
Sodium oleate

C\(_{20}\)H\(_{44}\)BrN  
Tetrapentylammonium bromide

C\(_4\)H\(_9\)O\(_4\)  
Butyl sulphate

C\(_5\)H\(_9\)NaO\(_2\)  
Sodium valerate

C\(_6\)H\(_{14}\)O\(_2\)  
Butoxy ethanol

CAPEX  
Capital expenditures

CNG  
Compressed natural gas

C\(p\)  
Heat capacity

C\(st\)  
Distance of sparger from the bottom of reactor

CTAB  
Cetyl trimethyl ammonium bromide

C\(tr\)  
Distance of impeller from the bottom of reactor

DI  
Dual impeller

xxxiii

CHAPTER 1

INTRODUCTION

Planetary request will increase considerably in the following decades as population of the earth proliferates. US DOE 2016 International Energy Outlook, claims that the universal energy consumption will augment from 549 quadrillion BTU in 2012 to 815 quadrillion BTU in 2040, indicating 48% increase. The primarily countries that contribute to this augmentation in demand are non-OECD developing economies, such as China and India, where request is prognosticated to raise by 112% between 2010 and 2040 [1]. Whereas the expectation is that non hydrocarbon sources such nuclear and renewables can generate more power the following years, the quantity generated is presumably still far from meeting the huge augmentation in energy request. By 2040, the prognoses nominate that more than 76% of energy will be of carbon based source, despite expansion in not carbon sources [2]. Therefore, unconventional sources will have a significant place and more specifically, gas hydrates will play the primary role [3].

There are certain sets of high pressure and low temperature conditions under which gas hydrates are formed [4,5]. Methane storage enclosed in cages formed by water molecules via gas hydrates is highly auspicious due to its many advantages [6,7]. Its benefits comprise (i) notable storing action capacity of 165 volumes of methane in a unit volume of hydrate; [8] (ii) temperature and pressure conditions of hydrate formation and storage compared to conventional natural gas storage methods; (iii) relevant comfort and nigh complete recovery of SNG; (iv) ecologically acceptable method utilizing only water with very low concentrations of gas hydrate promoters; and (v) non peril manner of NG storage as it is “non-eruptive” [9,10].
Fast hydrate formation is very crucial for the mercantile performance of SNG technology. Kinetics of hydrate formation can be augmented firstly by appropriate chemicals (promoters) such as surfactants and amino acids, that assist in ameliorating the rate of hydrate formation, secondly by new reactor design that assists at ameliorating gas-liquid contact to manage a higher rate of hydrate formation and thirdly by combination of both approaches. Current experimental and modelling efforts try to manage the kinetic augmentation during hydrate formation by implementing any of the previous listed ways in order to allow the process of SNG technology on a large scale [11-22].

As an outcome this thesis focuses on the following topics:

Chapter 2 is a theoretical approach of gas hydrates and describing the fundamental knowledge about gas hydrates such their chemical structure, properties, location of gas hydrates in nature, utilization of gas hydrates, gas hydrates in tanks and in pipelines, gas hydrates as source of energy and on-going research about gas hydrates.

Chapter 3 makes a summary about hydrate inhibitors and promoters. There is a literature review in the three different kind of inhibitors such as thermodynamic inhibitors, kinetic inhibitors and anti-agglomerates and also presents past and recent chemicals that have been used as promoters.

Chapter 4 presents a definite statement of the current issues

Chapter 5 presents the experimental procedures that took place for three different applications, namely experiments with pure methane, mixture gas and amino acids.

Chapter 6 discusses the experimental results of hydrate formation tests in which methane was used as hydrate forming gas. 24 experiments with different impeller – baffle configurations under fixed rotational speed (500 rpm) were conducted. The graphs of pressure and temperature versus time, torque versus time, moles versus time and hydrate formation are presented.
Chapter 7 is dedicated to discuss the experimental results of hydrate formation tests with methane-propane (95%-5%) mixture as hydrate forming gas. Again, 24 experiments with different impeller – baffle configurations under fixed rotational speed (500 rpm) were conducted and the same interpretation procedure of methane tests is followed.

Chapter 8 presents the interpretation of experiments with the same mixture gas (95 % methane – 5% propane), but this time with some amino acids in water phase. 6 experiments, 5 with different amino acids and one with pure water, were conducted.

Chapter 9 presents the conclusions of this thesis.

Chapter 10 presents the recommendations for future studies.
CHAPTER 2

GAS HYDRATES

Gas Hydrates (GH) commonly called, as clathrates are non-stoichiometric crystalline place when water forms a cage-like structure around small size gas molecules [23]. Gas hydrates form as the constituents get in touch with at low values of temperature and high values of pressure [24]. Gas hydrates are synthesized of water and principally the retainer gas compounds and elements: methane, ethane, propane, iso-butane, normal butane, nitrogen, carbon dioxide and hydrogen sulfide [23]. Makogon [25] exemplified methane hydrate formation reaction as:

\[
CH_4 + nH_2O \leftrightarrow CH_4.nH_2O + \Delta H_1 \quad (1.1)
\]

\[(\text{Methane}) \quad (\text{Liquid}) \quad (\text{Hydrate})\]

\[
CH_4 + nH_2O \leftrightarrow CH_4.nH_2O + \Delta H_2 \quad (1.2)
\]

Where \(n\) is the hydration number approximately equal to 6.1 for methane (\(CH_4\)) hydrates [5]. The hydrate configuration reaction is an exothermic operation, which generates heat while the hydrate dissociation reaction is an endothermic operation, which imbibes heat. The heat of modulation of methane hydrate from methane and liquid water (\(H_2O\)) is \(\Delta H_1=54.2 \text{ kJ/mol}\) and the heat of modulation of methane hydrate from methane and ice is \(\Delta H_2=18.1 \text{ kJ/mol}\) [26].

In methane Hydrate (MH) reservoirs in nature, temperature and pressure conditions have to be in MH stability region in the initial phase. In order to segregate MH and manufacture gas from a MH reservoir, pressure and temperature conditions should be in MH separation area. Consequently, three methods of thermal injection, depressurization
and inhibitor injection have been suggested as primarily operations for separating MH [27,28].

In depressurization operation, the bottom-hole pressure is diminished by a pump settled down hole and this low pressure is moved to reservoir to prompt the dissociation of MH. By diminishing the bottom hole pressure of a well, the reservoir pressure (Pr) in the contiguity of this well diminishes first. The temperature of reservoir diminishes along with dissociation of MH due to dissociation of MH because imbibes energy. The dissociation of MH ceases when the reservoir temperature concludes alike to the 3-phase equilibrium temperature analogous to the reservoir pressure shown in Figure 2.1.

![Figure 2.1](image)

**Figure 2.1** Temperature reductions along with the MH dissociation in depressurization method [27].

Although depressurization was suggested as a promising method, the methane recovery from a MH reservoir by this method highly relies on reservoir properties and is prognosticated to be up to about 60% even in the propitious occasion [29].

Thermal operation is the comprehensive phrase for the operations supporting the dissociation of MH by augmenting the reservoir temperature. This method also contains thermal stimulation method and thermal flooding method. The thermal stimulation
operations intend to the augmentation in the temperature near a well. These operations comprise a hot water circulation process, circulating hot water in a wellbore to increase bottom hole temperature. In thermal flooding, the heat such as hot water is injected from a well and is flooded toward other wells augmenting the degree of warmness and hence dissociating the MH between wells (hot water flooding method) [28,29].

From hot water circulation only a few per cent of methane retrieval is anticipated since bottom-hole pressure should be higher than inceptive reservoir pressure to circulate water. On the contrary in depressurization and other thermal methods approximately 100% of methane recovery is anticipated by synergistic effect of depressurization and heating if the conditions are favorable. However, since energy supplied is big enough, the quality of being appropriate of thermal methods is questioned from the point of energy ability. In the inhibitor injection method, important MH dissociation is not anticipated solely. Over and above, it should be hard to supply an inhibitor smoothly into a reservoir because of very low initial effective permeability to water. The effect of the inhibitor injection method, however, comes into doubt because of the high expenditure and dilution/dispersion of inhibitors [27,30].

![Figure 2.2 Gas hydrate production methods](image)

*Figure 2.2 Gas hydrate production methods [27]*
2.1 Properties of Gas Hydrates

Gas hydrates look like compact ice, can be burnt and they usually smell like natural gas. One cubic foot of methane hydrate can compress around 164 ft$^3$ of methane at standard pressure and temperature [31,32]. The density for gas hydrates varies, according firstly to the composition of the gas, secondly according to temperature T and finally due to pressure P, which they are used to form, hydrates.

The results show that the density of gas hydrate is a little bit lower than the density which has been measured in the laboratory. The results also propose that Young’s moduli of methane hydrate are higher than that of water ice [34].

2.2 Hydrate Structures

Water molecules compose the cavities, which are constituted of pentagonal and hexagonal faces, mold hydrates. The merging of different parts of alternative faces assists for the formation of different hydrate structures to the fact that geometric structures are notable to realize the nature of hydrates. Two structures (types) of hydrates are the most common in chemical and petroleum industry and these are, structure I (sI) and structure II (sII). Another structure (type) that is less ordinary than the two proceeding structures are the structure H [35]. The tetrahedral positioning of water molecules, which are held together by hydrogen bonds, is the common property of the three structures of hydrates. The tetrahedral bonded waters in hydrates resemble the tetrahedral positioning of water molecules in hexagonal ice, which is the most ordinary
solid form of water. The bond lengths of the hydrates vary only less than 1%. From the other side the angles between oxygen atoms deviate by less than 4 % [36]. The gas hydrate structure contains a number of polyhedral cages while ice includes a compilation of non-planar “puckered” hexagonal rings. Due to the difference the guest molecules inside the lattice can be trapped by the hydrates. It is obvious from the previous difference that the thermodynamic conditions required for ice formation and gas hydrate have the ability to form at temperature above the freezing point of water as long as the sufficient gas molecule and water is available [37].

![Image of gas hydrate structures](image)

**Figure 2.4 Structures of gas hydrates [5]**

The structures (sI, sII and sH) are described by the parameters of figure 2.4. The small cage (SC) of sI is connected in space by the vertices of the cages. The SC of structure sII the faces are shared. The spaces for both of the structures between the SC are formed by large cage (LC). As far as it concerns the structure sH the face sharing occurs in two dimensions such that a layer of SC connects to a layer of medium and LC [5,38]. The three structures of gas hydrate embody alternative guest molecules into a single cell but sH needs two different-sized molecules to form: one small molecule as a helping gas.
such as methane accomplishing the small cage and a large molecule [39]. Table 2.4 represents the structures of gas hydrates according to Sloan and Koh in 2008.

</table>

The ratio of water molecules to gas molecules within a unit cell is expressed by the hydration number (n). It has mutual connection to the cage occupancy (θ), as each unoccupied cage adds more water but no gas molecule to the equation, therefore a high n implies a low θ. The cage occupancy (θ) is significant to define the amount of gas captured in hydrates [29]. As far as, it concerns the presence of two or more gases, the crystal structure is depended not only by the size of the biggest quest molecule present
but also by the concentrations of the guests. Ethane suits into LC of both sI and sII. Methane as single gas also suits in both structures of sI and sII. If methane and ethane occurred together, both of them can be formed as sI or sII depending: firstly, on temperature, secondly on Pressure and lastly on relative concentrations of the potential guests. A mixture of methane and ethane at various conditions of P, T insist as sI if the CH$_4$ concentration stays below 72-75 mol% [40] or above 99.2-99.4 mol% [41]. Table 2.5 shows the guest molecules and hydrate cages; ratio of guest molecule diameter versus cavity diameter.

**2.2.1 Structure I**

Structure I gas hydrates contain 46 water molecules per unit cell arranged in 2 dodecahedral voids and 6 tetrakaidecahedral voids which can accommodate at most 8 guest molecules. The hydration number ranges from 5.75 to 7.67. The average hydration number in the Structure I hydrates is 6 and the lowest hydration value is obtained when all crystal units are occupied whereas highest value is obtained for large guest molecules that cannot fill small cage. Structure I hydrates are formed by gas molecules such as methane, ethane, carbon dioxide and hydrogen sulfide [5,23,32].
2.2.2 Structure II

Structure II gas hydrates contain 136 water molecules per unit cell arranged in 16 dodecahedral voids and 8 hexakaidecahedral voids, which can also accommodate up to 24 guest molecules. The hydration number is 5.67 when all crystal units are occupied, whereas 17 when large guest molecules are not able to fill the small cages. This allows inclusion of propane and iso-butane in addition to methane and ethane but not pentane [5,23,32].

2.2.3 Structure H

The rarer structure of gas hydrates, which contain 34 water molecules per unit cell arranged in 3 pentagonal dodecahedral voids, 2 irregular dodecahedral voids, and 1 icosahedral void, can accommodate even larger guest molecules such as iso-pentane. The hydration number of sH is 5.67 like sII. The structure H of gas hydrates was discovered by Ripmeester et al. in 1987 [42]. It is possible that Structure H was first prepared (but not found) by de Forcrand in 1883 during his laboratory experiments. Binary (double) hydrates with iso-butyl chloride or bromide as the big guest were mingled by de Forcrand, where these guest molecules were contiguous in size to iso-pentane, now known to be a sH hydrate former. Formation of this structure necessitates minor guest molecules like methane, nitrogen or carbon dioxide for the $5^{12}$ and $4^35^66^3$ cages, but the molecules in the $5^{12}6^8$ cage should be bigger than 0.7 nm but smaller than 0.9 nm like methyl cyclohexane. These hydrate structures consist of three $5^{12}$, two $4^35^66^3$ and one $5^{12}6^8$ crystal units in a unit cube. When the cages of structure H are concerned, there would be 6 gas molecules per 34 water molecules in other words, the guest to water ratio becomes 1: 5 $\frac{2}{3}$ [5,23,32].

2.3 Location of Gas Hydrates

More comprehension about gas hydrates operations initiated after 1920 when the pipelines commenced to transport methane from gas reservoirs. In low temperature there was obstruction in pipelines which sometimes put impediments for the gas to flow
through them. Primarily these obstructions were expounded as frozen water. The advisable designation about these obstructions was given in the 1930s, and it was hydrate. On the other hand, in 1946, Russian specialists claimed that the conditions and resources for hydrate formation and stability subsist in nature, in districts covered by permafrost and their first discovery suggestion was in Western Antarctica [25,34]. Figure 2.5 shows the marine and onshore hydrate locations. About 98% of the gas hydrate resources are concentrated in marine sediments, with the other 2% beneath permafrost. Seismic processes and scientific drilling programs are responsible for interfered gas hydrate accumulations (red) and discovered gas hydrates (blue) respectively [43].

![Figure 2.5 Natural Gas Hydrate Reservoir Distributions in the World](image)

**Figure 2.5** Natural Gas Hydrate Reservoir Distributions in the World [43]

Other regions that have been indicated for gas hydrates are Gulf of Mexico, Pacific Coast of Canada, North Slope of Alaska, Japan, China, India and in South Korea [45].

Boswell’s group suggested a new way to classify hydrate reservoirs and they divided in four categories. According to these scientists, their classification is based on geological framework and lithology of hydrate bearing sediments. The four significant plays that hydrates could be located were sand-dominated plays, fractured clay dominated plays; massive gas hydrate formations exposed at sea floor and low concentrations hydrates
disseminated in a clay matrix. It is also found that hydrates exist in fracture fillings in clay dominated systems in shallow sediments [26]. The natural gas hydrates in marine sediments are regulated by the hoardings of Particulate Organic Carbon (POC) which is microbial transformed into methane, the thickness of the gas hydrate stability zone (GHSZ) that methane (CH₄) can be ensnared, the sedimentation rate (SR) that checks the time that POC and the produced methane (CH₄) stays within the GHSZ [46]. Figure 2.6 presents the gas hydrate stability conditions for both marine and permafrost hydrates.

**Figure 2.6** Gas hydrate stability conditions for a) marine hydrates b) permafrost hydrates (Orange curve: hydrate equilibrium curve, Blue curve: thermal gradient curve) [47]

Recently, Wallmann et al. in 2012, introduced transfer functions to show the gas hydrate inventory in diffusion-controlled geological systems based on SR, POC and GHSZ thickness for two alterative plans: normal and full compacting sediments [48]. In Figure 2.7 is presented the global gas hydrate inventories in marine sediments.
Hydrates have changed derived the current semantic about untapped hydrocarbon source, as an icy compound in outer solar system environments, and as a manufactured material that is a contingent way for not dangerous storage and transport of natural gas [49]. Many tries of different researchers in the world that attempted to obtain the solution to the problem of natural gas transportation and storage in a solid hydrate state. It is safer to store or ship gas in hydrate state than liquefy it [50]. Parlaktuna and Gudmundsson first proposed storage and shipping of natural gas in 1992 in Trondheim University [51]. This idea continued by Stern et al. who made experiments and proposed an anomalous self-preservation effect of hydrates. Stern claimed that only mild refrigeration (268 K) was needed to maintain the hydrates for longer time at atmospheric pressure [49].

Hydrate formation is a key factor for safety reasons in deep water oil/gas production. In 2010 hydrate was the major restrained reason of the oil leak following blow out of the Macondo well in Mexico. Other utilizations of gas hydrates contain storage of natural
gas and hydrogen ($\text{H}_2$). The competence to store natural gas in the form of hydrate pellets has the tendency to be done where there is secluded gas in small quantities and the need for building a liquefied natural gas plant is not economic viable [52,53]. The storage and transportation of gas hydrates are to commercialization by developing and optimizing efficient production of large volumes/scale up of gas hydrate pellets [54]. Attempts have also been done to evolve gas hydrates for hydrogen storage applications. The hydrogen molecules conceive the small and the large cages of structure II of hydrates. Tetrahydrofuran (THF) which works as promoter molecule, it enables $\text{H}_2$ hydrates to be formed and stabilized at lower pressure conditions than those needed by pure hydrogen hydrates. The incentive in this occasion is to store $\text{H}_2$ in clathrates materials in as possible lower values of temperature and pressure as well as at high capacity [55,56]. Gas hydrates can be implemented to separation procedures such as separation of flue gas and desalination of water. Flue gases such as carbon dioxide ($\text{CO}_2$) are captured in gas hydrates while precluding nitrogen ($\text{N}_2$) and other not harmful molecules. There is no commercialization use until now [57]. On the other side desalination is very significant for fresh water for both domestic and agricultural factors. In the desalination procedure, gas hydrate will be formed by sea water such that salt ions are blocked [58,59]. Albeit that first time desalination procedure was proposed some decades ago, it is still unsearchable and it will be needed further research and evolvement to explore the technical and economic expediency of this process [60,61].

2.4 Gas Hydrates in Pipelines

The exploitation of gas hydrates seems beneficial to untie upcoming energy problems. Moreover, gas hydrates play a significant role in gas transportation and gas storage in pipelines, particularly in conduits and valves, gas hydrates are created and prevent the gas flow. This phenomenon is called “plugging” and congests high operational expenditures as well as vague not dangerous circumstances [62]. It is obvious that the gas hydrate formation in oil and gas pipelines is an unwelcome condition, undermining the flow assurance programs in addition to posing menace to the staff and equipment
Blocking by gas hydrates can be shunned in pipelines by the utilization of alternative operations of inhibition such as heating or insulating the critical pipeline expanses or by adding inhibiting chemicals e.g. methanol. These hydrate inhibition operations are both pricey and not environmental acceptable [62].

Various transportation options of natural gas from off-take include long pipelines transport, liquefied natural gas (LNG), compressed natural gas (CNG) of pressure between 207 and 248 bar (3,000 and 3,600 psi) and methanol. Long pipelines and LNG are the ordinary utilization. The unit expense of pipeline selection is obvious higher than LNG due to the demanded huge charge of refrigeration and liquefaction of boiled-off liquids and the high peril of over pressurization for LNG. Transportation by methanol and CNG evince unit costs which are similar to pipelines but these are in theory nowadays [64]. Water is of 90% composition of the hydrate lattice while other components constitute 10%. The solid hydrate may be formed at high pressures and low temperatures (even above the normal melting point of ice) due to the weak Van der Waals forces and the hydrogen bonding properties of water [65,66]. Below sea, gas transportation pipelines frequently have thermodynamically conditions to generate hydrates. Formed hydrates can obstruct pipelines, subsea transfer lines and in the event of gas kick during drilling, hydrate can be formed in the wellbore riser, blow-out preventer and choke-lines [67]. As far as it concerns the economic situation, expenses that originate from gas hydrates, cost billions of dollars ($) in upstream industry. Every year upstream industry tries to moderate these expenses with no stable solutions in focus [68]. Hydrates can also influence alternative types of natural gas pipeline’s internal corrosion which is a long term trouble through physical and chemical functions based on hydrate size, stage and contact period [69]. H₂S, CO₂ and Cl⁻ that are components of hydrate, are acidic gases which conduce to internal gas pipeline corrosion rate [70]. Methane, the major component of natural gas, also participates as a diminishing agent for metal corrosion [71]. Water is another known corrosive agent [72]. Corrosion apart from the financial aftermaths will also generate political and environmental corollaries and will lead to consolidate substitution of the pipe-length at extra production rate. The
corrosion types that could be initiated by physical means include cavitation, erosion, pitting, galvanized and stress cracking corrosion. Worldwide oil and gas industry instead to put efforts how to solve the problem about hydrates creation of corrosion (main problem), they insist to put efforts how to remove hydrates after its formation with so many discoveries about its properties and abilities to rapture a service pipe [73].

2.5 Gas Hydrates in Tanks

Natural gas is one of the significant energy resources and lately its worldwide consumption is promptly amplifying due to the growing demand for clean energy and environmental concerns. It is prognosticated that the natural gas demand is raised at an average rate of 2.4% annually until 2030 in the world [73]. Figure 2.8 shows the worldwide trend natural gas consumption up to 2025 [74].

![Figure 2.8 Worldwide natural gas consumption](image)

To satisfy such a demand, there are plans to transport natural gas to potential markets. Apart from transportation of hydrates through pipelines, there are other methods such LNG and CNG. In LNG occasion, natural gas is liquefied at atmospheric pressure and
temperature approximately 113K. Transforming natural gas to LNG decreases the gas to 160 of its volume permitting transportation by specialized LNG tanker ships over long distances. The storage of LNG is commonly guided in onshore facilities LNG carriers can also be profitable for shipping big volumes of gas over long distances [75,76]. Although offshore transportation of compressed natural gas CNG have been begun from long time ago up to lately, the studies and researches for commercial outcomes have not been successful. The main reason is the cost of the required pressure vessels. However, commercial CNG carriers are on the stage of the implementation [74]. In CNG projects, most of the capital investment is consumed on creating the ships. Due to the fact that LNG is complicated and capital intensive cooling and re-gasification, CNG loading and unloading terminals would conditionally be simpler and cheaper than those used for LNG [75]. Generally, it is obvious that the transportation of gas is cheaper by ships compared to pipelines [77]. Figure 2.9 presents the cost for gas transportation with different methods.

Figure 2.9 Comparison of gas transportation with different methods [77]
2.6 Hydrates as Potential Source Energy

It is obvious that oil and gas industry face many problems in hydrate operations. All of efforts from researchers and companies have been spent about the determination of hydrate crystal structure, thermodynamic behavior, kinetics of hydrate formation and ways to face plug formations [78]. Potential reserves of gas hydrates are over $1.5 \times 10^{16}$ m$^3$ and are distributed all over the earth both offshore and onshore. If only 17-20% of this resource can be produced feasibly, it can be sufficient supply energy for 200 years [79]. More than 220 gas hydrate deposits have been discovered, more than a hundred well have been drilled and kilometers of hydrated cores recovered. The most significant fact is not the amount of gas hydrate potential reserves but the volume of gas that can be commercially produced. The rate of modern civilization development in future hinge on different considerations but the quality and especially the quantity of energy will be among the most significant considerations. The data presented in figure 2.10 shows that in the 20$^{th}$ century the energy consumption came from coal instead of oil and gas [80].

![Figure 2.10 Energy consumption in the 20$^{th}$ century [81]](image-url)
The winning performance of natural gas transport like NGH may confine the operational expense drastically by shunning extremely low temperature process cost in LNG production and compressing demand in CNG production. On the contrary, firmness of the end product is a significant disquiet. It has been demonstrated that the firmness of the end NGH product remained stable up to 2 years in solid hydrate form in cold climates such as Russia and Norway [82]. It should not be forgotten that natural gas, primarily methane, is a splendid fuel for combustion many reasons. Methane generates less carbon dioxide per mole than any other fossil fuel when it is used as fuel. Figure 2.11 is summarizes the world energy balance until 2050.

![Figure 2.11 World Energy Balance [81]](image)

Thus, it can decrease the quantity of emissions originating in human activities of carbon dioxide gas, which may cause a greenhouse effect. Moreover, the quantity of fossil fuel in hydrate form is around double as large as in all other fossil fuels combined [83]. In Figure 2.12 is depicted the timeline graphs for the essential gas hydrate projects worldwide.
Natural gas hydrates are more evenly distributed on the planet than sources of hydrocarbons. The most crucial anxiety is the generation of highly-effective technologies of transporting the natural gas from its solid state into free gas [79].

2.7 Motivation of Studying Gas Hydrates

It is obvious over the past years that complexity and important inability there are in the relationship between crystal structure and size of hydrate formers if more than one gas is present. This makes important the search about the structural information together with thermodynamic parameters, especially in multicomponent. Nowadays importance inhydrate persistence and decomposition requires application of new technologies that permit acquiring high resolved structural and statistically important crystallizes size information. Moreover, new information about thermodynamic behavior and kinetics of hydrate formation will play significant role in the researcher’s future studies [32]. Figure
2.13 indicates that gas production from gas hydrates are still at the early stages of development.

![Technology maturity curve of gas hydrates](image)

**Figure 2.13** Technology maturity curve of gas hydrates [85]

It is apparent that gas hydrates postulate more research to be comprehended, and this is indeed taking place. Willingness and persistence of both scientists and industry will optimistically take gas hydrates away from the legendary cloud that covers them, to something closer to a well-comprehended actuality [86]. Figure 2.14 shows the dispensation of organic carbon in earth blocking scattered organic carbon such as kerogen and bitumen.
Figure 2.14 Distribution of organic carbon in earth excluding dispersed organic carbon such as kerogen and bitumen. Modified from different sources [86]
CHAPTER 3

GAS HYDRATE INHIBITORS AND PROMOTERS

Formation of gas hydrates is known to causes rigorous problems in wellbores and more specifically in drilling [87], well completion [88,89] as well as transportation through gas pipelines [90,91]. Because production goes into deeper water, hydrate control grows in importance. Ideally, operators want total hydrate control without the problems associated with Thermodynamic Inhibitors (THI) and/or Low Dose Hydrate Inhibitors (LDHI) [92].

Kinetics of hydrate formation is always a significant scientific subject for more explorations. Since this scientific field is not well comprehended, various theories and models have been evolved explicating the mechanisms of hydrate formation. Miscellaneous correlations have been introduced in the literature for prognosticating the hydrate generation conditions. These correlations can be categorized into five major processes [93]. The first method is K-value method which uses the vapor-solid equilibrium constants for predicting hydrate forming conditions [94]. The second method is Gas-Gravity plot developed by Katz [95]. The third method consists of empirical correlations developed according to the following form by Holder [96] and Makogon [97] for selected pure gases. The fourth method contains the charts of permissible expansion that natural gas can undergo without risk of hydrate formation. These charts were redrawn with the aid of the gas gravity charts using the Joule Thomson cooling curves [98]. The fifth method is based on statistical thermodynamic approach developed by van der Waals and Platteeuw and accounts for the interactions between water molecules forming the crystal lattice and gas molecules [99]. However new hydrate phase measurement methods such as Raman, NMR and Diffraction
Spectroscopy have enabled van der Waals and Platteeuw model corrections to provide predictions which are almost accurate as the measurements themselves [100]. Apart from these five methods Ostegaard in 2000 presented an idea similar to gas gravity idea practicable to all reservoir fluids, in the attendance of distilled water from natural gas to black oil which requires simply knowledge on the specific gravity and the concentration of the hydrate forming components in the system. The effect of non-hydrocarbon gases such as CO₂, N₂ in the petroleum fluid can be taken into account for the above approach [101].

Hydrates may be formed in the drilled wells if fresh water based drilling fluids are used in low temperature and pressure intervals [102]. In water-based drilling muds, hydrates can defy difficulties in two ways. The first way is when hydrates create a ‘plug’ or solid mass in wellbore. The plug will start from areas with little or no circulation such as choke lines; kill lines and blowout preventers (BOP). The second way where hydrates cause problems with drilling mud comes from their physical makeup. The loss of water from mud causes flow properties to impair strictly [103]. Consequently, stunting the generation of gas hydrates is an essential problem in upstream industry. There are two selections to answer this exigent situation: hydrate avoidance (no entry in hydrate domain) or hydrate management (operate with risk in hydrate domain). The management of hydrate obstacle comprises actions that are shown in figure 3.1. [104].
Hydrate management strategies [104]

Through any of these actions can be efficacious in inhibiting hydrates, some may not be attainable or covetable for deep water operations. For example, dehydration is weak as action for subsea wells or small platforms with limited space. Heating and insulation can be used independently or jointly; however, it may not be cost effective for longer flow lines to convey high GOR (gas/oil ratio) fluids. Chemical inhibition is by far the most commonly used method for audit hydrates [105].

The chemical methods can be divided in two main categories thermodynamic inhibitors and low dosage inhibitors. The most common thermodynamic inhibitors are the organic compounds such as glycols (MEG, DEG, TEG). Other known thermodynamic inhibitors are the salts (NaCl, CaCl₂, CaBr₂ etc.) [106-110]. Low Dosage Inhibitors are divided in two categories: kinetic inhibitors (KHS) and anti-agglomerates (AAs). Prominent kinetic inhibitors are polymers such as PVP, TBAB, amino acids such as Tyrosine, salts with two or more n-butyl, n-pentyl, and iso-pentyl groups, copolymers and similar ones [111,112]. Moreover, well known anti-agglomerants are surfactants such as LABSA anionic type, DAM cationic type and Ethoxalate non-ionic and salts such as NaCl and similar ones [113]. Figure 3.2 shows the different functions of hydrate inhibitors.
3.1 Thermodynamic Inhibitors

Many researchers such as Parrish and Plausnitz in 1972, Sloan et al. in 1976, Robinson in 1976, 1977 and 1980, Holder in 1980 and John in 1980 discussed the thermodynamics of hydrate formation. All the researchers, apart from John et al., made use the statistical thermodynamic theory presented by van der Waals and Platteeuw in 1959. With the exception of Sloan in 1984, all previous works have been restricted to selected parts of general multiphase problem; and not the multiphase problem within a molecular thermodynamic framework [114]. Hydrates, which are components with low molecular weight, are in equilibrium with water at low temperature and high pressure. Water molecules form regular crystalline lattices that include cavities. These cavities encage gas molecules that stabilize the lattice by van der Waals forces [115].

Inhibitors such as methanol act by lowering the fugacity of water of water in coexisting phases; as result hydrates are formed at lower temperatures and higher pressures than those encountered in the absence of methanol. This behavior is analogous to the freezing point depression of water by methanol [116]. Hydrates are most frequently encountered
in gas transportation and processing. Well known method to inhibit generation of hydrates in pipelines, is to use ‘thermodynamic’ inhibitors, such as methanol, broadly at high quantities (e.g. 40 vol%). THIs functions by alternating the hydrate formation phase limit elsewhere from the temperature and pressure conditions of the process in question, augmenting the driving force demanded for hydrate generation (see figure 3.3). Nevertheless, the implementation of thermodynamic inhibitors is both not good from financially perspective and ecologically hazardous and not acceptable. Nowadays that upstream sector goes to profound waters where hydrates prefer to be generated; up to 60 vol% methanol could be demanded for valid hydrate audit [117].

**Figure 3.3** Phase boundary of methane hydrates [117]

Historically as it has already mentioned the most common thermodynamic hydrate inhibitors are glycols and salts. The thermodynamic inhibitors shift the formation of hydrates curve to the left so the system can bear lower temperatures and high pressures [118,119]. Apart from glycerol, Hale and Dewan [120] reported the felicitous use of salt together with glycerol so as to impede the hydrate formation in 1990. Quigley and
Hubbar conducted experiments with high concentrations of salt, alcohols, surfactants and their mixtures at 3,100 ft water depth and 5°C sea floor. Inhibition capacity of 26-wt % NaCl and its combinations proved safe choice apart from the mixture of 26-wt % NaCl and 20-wt % glycerol, which did not procure adequate safety at these conditions. Generally, salts are much more corrosive and less effective than methanol or glycols as pure thermodynamic inhibitor [121].

In 1992 Kotkoskie et al. [103] run a series of experiments with three different salts as thermodynamic inhibitors. The outcomes show that (NaCl) and sodium bromide (NaBr) have crucial inhibiting properties and could displace the equilibrium. Another salt, calcium chloride (CaCl₂) induces desirable hydrate formation, but due to the corrosive outcomes, it is not preferable. Nevertheless, CaCl₂ acquires the best result for inhibition among the pure salts. Howard in 1995 nominated how to calculate the effect of salts on hydrate formation temperature by freezing point depression data for the salts. Howard used the formula that was presented by Sloan in 1990. With this formula you could foretell the outcome on hydrate formation temperature for any natural gas [122]:

\[ T_{eq,s} = T_{eq} * \Delta T_{freezing} \]  \hspace{1cm} (3.1)

where:

\[ T_{eq,s} = \text{hydrate equilibrium temperature in brine, } ^\circ\text{C} \]

\[ T_{eq} = \text{hydrate equilibrium temperature in water, } ^\circ\text{C} \]

\[ \Delta T_{freezing} = \text{freezing point depression by brine, } ^\circ\text{C} \]

In 1997 Ebeltoft et al. tested the salt polymer system by comparing drilling fluids in terms of hydrate inhibiting outcome. Apart from the three salts that were used before (NaCl, NaBr, CaCl₂), potassium chloride (KCl) was used for the first time. The effect of glycol was under consideration as thermodynamic inhibitor. The best outcomes depended on composition of salt and glycols were the 10-wt % ethylene glycol+15-wt % NaCl+5-wt % KCl [123]. Fadnes et al. in 1998 assured that salts could behave as
thermodynamic inhibitors. They ionized the solution and interacted with water molecules by bonds, resulting as clusters. Hence, they formed clustering around the polar solute molecule and the potential hydrate formation molecule diminished in water. This procedure is the “salting out” which was mentioned before [118].

Dominique Richon (2006) used thermodynamic inhibitors that have been used before such as salts of (NaCl) and (KCl) together with thermodynamic models. Generally, there was a good agreement between independent experimental data (using reliable isochoric technique) and predictions demonstrated the reliability of the developed model [108,124]. Calcium Chloride (CaCl$_2$) was also used as thermodynamic inhibitors together with ethylene glycol in different concentrations. Reliable hydrate dissociation data for quaternary system CH$_4$-H$_2$O-CaCl$_2$-EG had been estimated at pressures up to 50 MPa. Also in CaCl$_2$ salt there was an acceptable accordance between model prognoses and irrespective experimental data on; water freezing point depression, vapor pressure reducing, salt solubility and hydrate constancy zone [109].

Another effort of thermodynamic inhibitors took place in 2009 again from Dominique Richon et al., where they used salts such as Sodium Bromide (NaBr), Potassium Bromide (KBr), Calcium Bromide (CaBr$_2$), Potassium Carbonate (K$_2$CO$_3$) and Magnesium Chloride (MgCl$_2$) for different concentrations and temperatures. The acceptable agreements for dissociation conditions between the experimental data measured and the data reported in literature helped to confirm the reliability of the experimental results for all salts, but MgCl$_2$, which showed an unusual behavior at higher concentration [125].

Methanol is the most common thermodynamic inhibitor at oil/gas complex due to its availability and cheapness as chemical compound. Nevertheless, it is not implied that methanol is the most appropriate in use. Availability, low cost and guaranteed outcome from its use are not always the determining factors for the choosing of an inhibitor. Methanol has very high toxicity contiguously to ethyl spirit. Moreover, due to its high toxicity there is problem in recycling the water solutions of methanol. Hence, this
situation is required unprecedented security measures at purchase, transportation storage and use of methanol that are comparable to the cost of product itself [126].

3.2 Kinetic Inhibitors

Kinetic Hydrate Inhibitors (KHI s) are Low Dosage Inhibitors (LDIs) that are added at low concentrations (<1-wt %) and they do not influence the thermodynamics of hydrate formation [127]. However, these kinetic hydrate inhibitors dissipate hydrate particles as they generate such as special surfactants or some of them suspend hydrate formation for more chronic bedding by prolonging the induction time for hydrate generation [128]. KHI s are generally water-soluble polymers. However, there are a number of non-polymeric hydrate crystal growth inhibitions that are poor anti-nucleates (e.g. C_{20}H_{44}BrN, C_{6}H_{14}O_{2}). KHI s allow transportation of hydrate forming fluids for specific chronic bedding limits up to hydrates commence to form. The chronic bedding limit to the generation of the first hydrate crystals is called induction time [129,130]. A wide range of Operating Expenses savings, possible extended field lifetime and multi-million-dollar Capital Expenditures savings, are financial leaders for selecting LDHIs as a substitute of other hydrate impeding practices [131].

Good performance of KHI s has been noticed for different fluid systems such as gas, condensate and black oil [132,133]. In case it was necessary for actual multiphase reservoir fluid in oil and gas pipelines, salts could be added to make saline solutions and heptane or decane could be added as a liquid hydrocarbon phase [134-136]. Apart from multiphase applications, KHI s are also used during drilling while compromised to the drilling fluid [137,138]. Porous media such as silica sand have also been tested. Interstitial pores can be very different from that in the usual liquid gas hydrate system in the hydrate formation dissociation conduct. Kelland in 2014 presented a comprehensive research on gas hydrate control with special target on synthesis, chemistry and laboratory performances on new KHI s. On the other hand the industrial research has been completed by Klomp [139,140].
Apart from chemistry of KHIs, many researchers targeted the tools and the processes for experimental KHIs in natural gas hydrate systems the previous years. KHIs inhibition based on both experimental and computational data are: Antifreeze proteins (AFPs) [141-143], Ionic Liquids (ILs) [144,145], Tetrahydrofuran (THF) or cyclopentane hydrate systems [146-149], Recycling [150] or removal [151] of KHIs for future field applications. For upstream applications implemented three different KHIs polymer groups such as Poly (N-vinyl lactam) polymers [152-158], hyper-branched poly (ester amide) [159,160] and N-Isopropylmethacrylamide [161] (IPMA) polymers and copolymers.

Other polymeric KHIs that have been tested contain pyroglutamate polymers, maleic copolymers and alkyl amide derivatives [163,164], polyalkyloxazolines [165], polymaleimides [166], polyallylamides [167], polyaspartamides [168,169] modified starch, starch derivatives and proteins. Recently, sodium chloride, an inorganic and well-known THI, was mentioned to possess kinetic inhibition properties toward hydrate formation in porous media. Nevertheless, it seems to only slow the growth rate of hydrate formation and has no influence on the induction time [170].

In late years, amino acids play important role as kinetic inhibitors but still in the lab environment. Hydrophobic amino acids such as glycine, L-alanine, and L-valine to be applied as thermodynamic hydrate inhibitors (THIs) [171]. L-serine, L-proline, aspartagine, L-threonine, L-valine, L-histidine, glycine, alanine, serine, proline, arginine, L-leucine, L-tryptophan, Lysine, valine, methionine, phenylalanine, alanine, serine, glycine+ethylene glycol and glycine+1-ethyl-3-methyl limidazolium chloride have also been used as inhibitors for methane gas hydrates [172]. Other amino acids that have been used for CO₂ hydrate inhibition are L-phenylalanine, L-cysteine, L-methionine, L-threonine, proline, glycine, threonine, glutamine, histidine, alanine, arginine, L-methionine, L-norvaline, L-norleucine, 2 amino heptanoic acid, n-hexylamine, lysine, phenylalanine, methionine, Cysteine, isoleucine, aspartic acid, asparagine, histidine, L-histine, PVP and L-Tyrosine [173,174].
Figure 3.4 Structures of amino acids [175].

In field applications, there were enough examples that the use of kinetic inhibitors leading to positive outcomes such as in GoM in 1990 [176] and the other in Peru in 1995 [177,178]. In both occasions [VIMA/VCAP] was injected to audit hydrates.

3.3 Anti-agglomerates

Anti-agglomerates low dosage inhibitor (LDHI’s) confers to researchers and companies an additional tool for checking the formation of hydrates in their systems. Unlike the kinetic and thermodynamic inhibitors, anti-agglomerates LDHI’s inhibit hydrate plugging rather than hydrate formation. Anti-agglomerates permit hydrates to form but retain the particles small and well dissipated. In other words, AAs have a hydrophilic head and a hydrophobic tail [179]. According to Koh et al. in 2002, AAs were described as emulsifying agents, which suspend hydrate crystals in condensate because the ends of AA molecules have qualities attractive to both hydrates and oil [180]. The amount of
AA required for hydrate blockage impeding is almost only a fraction of the THI dosage and therefore AA does not appreciably shift the hydrate thermodynamic equilibrium curve of the system. Due to the mechanisms by which AA works, its felicitous application requests the presence of hydrocarbon phase [181]. AAs as chemicals are polymers and surfactants which are added at low concentrations (<1 wt %). The first try to control the hydrates by the use of surfactants was by Yuliev in 1972 before any other relevant work has been published [182]. In the last years of 1980 and the early years of 1990, Institute Francais du Petrole (I.F.P) made experiments with many surfactants but only some of them were for commercial use. Some of the chemicals were ethoxylated sorbitan monolaurate, ethylene diamine based block PO-EO copolymers, polymers of isobutylene succinate diester of monomethylpolethylene glycol which could behave as anti-agglomerates [183].

![Figure 3.5 Structure of the ethoxylated sorbitan tween surfactants. The EO groups are randomly distributed over the four available sites [184]](image)

Apart from I.F.P, Shell has also patented some other classes of surfactants. These include alkyl aromatic sulphonates (Dobanax series) and alkyl polyglycosides (Dobanol). Stat Oil, SINTEF and NTH had published work on surfactants containing alkyl phenylethoxy lates. One of these, Berol 26 showed logical outcomes in the high-
pressure wheel, but the concentrations used were very high (up to 7 wt. %). Sodium
dodecyl sulphate (SDS), some polyacrylamides and tyrosine gave not desirable
outcomes [185]. More specifically Exxon presented a formal request for two patents in
1994 about surfactants with hydrophobic tail of 12 carbons or less as AAs [99] and in
1995 covered their use as synergists with KHI polymers [186]. The surfactants that were
used by their own in the THF ball-stop rig and they had desirably performance contained
C₄H₈O₄, C₅H₉NaO₂, zwitterionics such as butyl-dimethyl ammonium butylene sulfonate
and C₁₆H₃₅NO. When they also used together with alkyl amide polymer KHI, they gave
desirably outcomes [187].

BJ Unichem Chemical Services found that polyether polyamines and polyether diamines
lowered the blocking temperature or gave a longer time to blocking than a test with no
additives [188]. BJ Unichem also patented quaternized polyether polyamines by reaction
of polyamines with long chain alkyl bromide. These products behaved better in the THF
hydrates [189]. At least four field applications have been reported in gas wells. It is
difficult to categorize BJ’s products or indeed understand the mechanism for their action
[190]. Gao tested hydrate formation with an anti-agglomerate hydrate inhibitor and
methanol, which was conducted on rocking cell apparatus to investigate the feasibility,
and the strategy for managing gas hydrates at high water cuts with AA. Outcomes
showed that brine salinity plays important role in hydrate management at water cuts with
AA. A minor raise in salinity causes a step change in AA performance. It was also
noticed that the addition of a small dosage of AA could considerably retrench the
amount of methanol required for hydrate blockage anticipation; in case AA reaches, its
water cut limitation. Outcomes declared that sub cooling is not an accurate term in
depicting the inconvenience of treating hydrate problems with AA technology [191].

Swanson et al. [192] studied the implementation of LDIHs in Gulf of Mexico. All kind
of inhibitors were used such methanol (THI), two anti-agglomerates and at the end
kinetic inhibitors. The anti-agglomerates behaved successfully until the water cut
increased to 50% so there was the necessity for the kinetic inhibitors. According to field
data, there was a thorough analysis of benefits and drawbacks for both anti-agglomerates and kinetic inhibitors. Table 3.1 shows the analysis of LDIHs [192]

### 3.4 Hydrate Promoters

Surfactants can also play the role of kinetic promoters. Kalogerakis et. al was the first that investigated the performance of surfactants in methane hydrate formation without any influence in the thermodynamics [193]. Anionic surfactants that have been used to promote methane hydrates are LABS, DBSA, SDSN), LDS, SO, SHS), SDBS, STS, sand other sodium alkyl sulfates like sodium butyl sulfate [194-198]. Cationic surfactants that play the role of promoter in methane hydrates are DAH, HTABr, CTAB, DN₂Cl while ENP, tergitol have also been tested successfully as methane hydrate promoters [199-203]. Another group of chemicals that are used as hydrate promoters are amino acids. Hydrophobic amino acids such as glycine, L-alanine, and L-valine to be applied as thermodynamic hydrate inhibitors (THIs) [204]. L-serine , L-proline, asparagine, L-threonine, L-valine, L-histidine, glycine, alanine, serine, proline, arginine, L-leucine, L-tryptophan, Lysine, valine, methionine, phenylalanine, alanine, serine, glycine+ethylene glycol and glycine+1-ethyl-3-methy limidazolium chloride have also been used as inhibitors for methane gas hydrates [205]. Other amino acids that have
been used for CO₂ hydrate inhibition are L-phenylalanine, L-cysteine, L-methionine L-threonine, proline, glycine, threonine, glutamine, histidine, alanine, arginine, L-methionine, L-norvaline, L-norleucine, 2 amino heptanoic acid, n-hexylamine, lysine, phenylalanine, methionine, Cysteine, isoleucine, aspartic acid, asparagine, histidine, L-histine, PVP and L-Tyrosine [206,207].

Polymers and starches also have been tested successfully as hydrate promoters. Polymers that have been used for promoting hydrates are soluble hydroxyethyl cellulose [208], poly (2-acrylamido-2-methylopropane sulfonic acid and poly (acrylic acid) [209] and poly vinyl alcohol (PVA) [210]. Starches that successfully functioned as hydrate promoters are potato starch [211], xanthan gum and starch [212], and Maize starch [213].
CHAPTER 4

STATEMENT OF PROBLEM

For decades, oil and gas industry considered natural gas hydrates as nuisance since hydrates have the potential to plug the production lines, pipelines and stop the production which can be resumed by costly operations. After the discovery of natural gas deposits in deep sea but shallow sea bed formations and permafrost regions, oil and gas industry started to study on the production of natural gas from hydrate bearing formations. But, hydrates also exhibit other characteristics which make them as the potential players of some industrial processes.

Owing to their high gas storage capacities (1 m³ solid hydrate can contain 150 – 170 Sm³ of gas) and the long-term stability of hydrate crystal structure at standard refrigeration temperatures and atmospheric pressure, oil industry started to look at the possibility of using hydrates as gas storage and transportation media.

Among several other factors to make the storage and transportation of gas in hydrate form, hydrate formation rate has crucial importance. The faster formation of hydrates in a hydrate forming reactor can play important role on the economics of operation. Good mixing of hydrate forming components (gas and water) can accelerate the formation process. This can partly be achieved by correct selection of tank interiors. Several water soluble chemicals can also be used to alter the hydrate formation rate. This study aims to promote hydrate formation by investigating the effects of impeller – baffle configurations, and use of water soluble chemicals on the rate of hydrate formation. In that respect, two types of impellers (up-pumping pitch blade turbine and Rushton
turbine) were utilized. As baffles, full, half, surface and no baffle alternatives were studied. As water soluble chemicals five different amino acids were tested.
CHAPTER 5

EXPERIMENTAL SET-UP AND PROCEDURE

5.1 Experimental set-up

An experimental set-up designed and constructed to carry out the kinetic studies of hydrate formation. The schematic diagram of the experimental set-up is shown in Figure 5.1. Five main components of the experimental set-up are:

1. Reactor
2. Control Unit
3. Cooler – controller
4. Data acquisition system
5. Cold room

Details of each main component are described in the following paragraphs.

5.1.1 Reactor

Two different stirred-tank reactors, one high-pressure steel reactor and one medium-pressure polymethyl methacrylate reactor, have been designed and built to carry out studies on the scale up of gas hydrate formation. The high-pressure cylindrical AISI 316 L stainless steel reactor has internal dimensions of 150 mm in diameter and 312 mm in length, and total available volume of 5.7 liter. It was designed for working pressures up to 150 bars. Figure 5.2 and Figure 5.3 show different components of the reactor. Those components namely are; pressure transducers, thermocouples, gas injection valve,
cooling water, shaft, baffle, impeller, servo motor and gear mechanism. The functions of each item are as follows:
Figure 5.1 Experimental set-up for hydrate formation
Figure 5.2 High-pressure stainless steel reactor

Figure 5.3 Some components of High-pressure stainless steel reactor
**Pressure transducers**: There are five ports (three on top flange and two on the main body of the reactor) on high-pressure steel reactor to attach the measuring devices and gas injection valve. Two pressure transducers with measuring range of 0 – 100 barg and accuracy of ±0.25FS % are attached to the top flange of the reactor to measure the pressure throughout the hydrate formation tests.

**Thermocouples**: Two thermocouples, one mineral insulated type TW/T (Threaded Type Thermowells) with accuracy of ± 0.2 % and one Pt100 with accuracy of ± 0.25% are attached to the ports at the main body of the reactor to measure the temperature throughout the hydrate formation tests. Those ports are located at a level in the main body that thermocouples are always in contact with liquid.

**Gas injection valve**: This needle valve is connected to the top flange of reactor to facilitate the gas injection into reactor which already contains distilled water to form hydrate. Gas is supplied from high-pressure gas bottles through pressure a regulator that provides adjustment of the pressure to the gas injection line.

**Gear mechanism**: The gear mechanism makes it easier to empty and clean the heavy reactor after each experiment. Reactor and gear mechanism are placed on a frame to make the easy handling of reactor.

**Servo motor**: One of the characteristic components of hydrate formation experiments is the mixing of hydrate forming liquid and gas to maximize the interfacial area between hydrate forming components (gas and liquid), thus minimizing mass transfer barriers. Both reactors that are used in this study are batch reactors equipped with different types of impeller – baffle configurations to provide efficient mixing. Rotation of impeller in this study is achieved by a High Inertia permanent-magnet synchronous motor (Siemens model SIMOTICS S-1FL6). Rotational speed of the motor is kept constant at 500 RPM throughout the study.

**Cooling water**: Relatively high rotational speed of shaft attached to servo motor created frictional heat at the early trials of experimental study. In order to overcome this
drawback of the system, a cooling water circulation system was added to remove the heat around the shaft.

**Shaft, impeller and baffle:** Shaft is a hollow pipe made by steel AISI 316L with an inner diameter of 6 mm and was attached to the servo motor. A one mm hole was opened on the shaft at a level close to top of the flange (within gas bearing section of the reactor) to allow the induction of gas through the shaft. A sparger was attached to the tip of the shaft to distribute the induced gas within liquid.

Two different types of impellers, namely Pitch-Blade-Turbine (PBT) and Rushton Turbine (RT) were used. They were made by acrylonitrile butadiene styrene (ABS) plastic and printed by a 3D printer. The effects of type of impellers on hydrate formation was studied with single impeller (SI) or dual impeller (DI) arrangements. In case of single impeller arrangement, the impeller is attached on the shaft to a position just above the sparger to break down the gas bubbles efficiently. This corresponds to a distance of 6.6 cm from the tank bottom. Figure 5.4 and Table 5.1 give the dimensions and position of mixing elements during single impeller experiments. There are four types of impeller arrangements in case of dual impeller experiments, PBT-PBT, RT-RT, PBT-RT and RT-PBT. In the first two arrangements the same type of impellers are used but in the remaining two, which are called as Dual Mixed Impellers (DMI), two different types of impellers are used. Figure 5.5 shows all impeller arrangements used in this study.

The shaft and baffles are made of AISI 304. Baffles are used to provide axial motion and to eliminate vortex formation in the reactor. Three different baffles were used in this study. These are named as Full-Baffle (FB), Half-Baffle (HB) and Surface-Baffle (SB) (Figure 5.6). Figure 5.7 shows the placement of baffles as reference to gas-liquid interface. Finally, Figure 5.8 shows the height of gas-liquid interface for single and dual impeller experiments as well as the placement distance of baffles with respect to this interface. As seen, the gas-liquid interface is at 150 mm for single impeller experiments and 225 mm for dual impellers from the bottom of reactor (NB stands for No-Baffle).

As mentioned earlier, a second reactor – a transparent one – was designed and built to carry out some of the experiments of gas hydrate formation (Figure 5.9). The main body of the reactor is made of polymethyl methacrylate (PMMA) with internal dimensions of 80 mm in diameter and 310 mm in length, and total available volume of 1.56 liter. It was designed for working pressures up to 30 bars. There are two steel (AISI 316L) outer circular disks which are mounted in the main body of the reactor where there are 4 inlets for the pressure transducers and thermocouples. The top and bottom flanges are serving as servo motor receptacle and as the base of the reactor, respectively. Flanges and discs are mounted with 8 steel studs, hence to function as the frame of the main body (Figure 10). Transparent nature of this reactor made it possible to make eye observations and video recording during hydrate formation. All other elements of transparent reactor are the same of high-pressure steel reactor except impellers and baffles. Only single impellers of PBTU and RT are used with 40 mm in diameter and no baffles are used (Figure 5.11). Table 5.2 give the dimensions elements of transparent reactor.

5.1.2 Control unit

This unit is mainly used to control the servo motor. This PLC unit has the capabilities to start / stop servo motor, set the duration, direction (clockwise or counter clockwise) and speed (RPM) of mixing. In addition, one of the pressure transducers and thermocouples are connected to this unit to record the data at every second. Finally, the voltage output of servo motor is converted to torque and recorded at every second.

5.1.3 Cooler – circulator

As mentioned earlier, rotation of shaft created heat due to friction which can retard / stop hydrate formation. In order to remove this heat, cooling water is circulated around the bearing of the shaft by a special design. A Refrigerated Cooling Bath is utilized to circulate anti-freeze added cooling water (2 °C) with a flow rate of 12L/min.

5.1.4 Data acquisition system

As explained in Reactor subsection, there are two pressure transducers and two thermocouples to measure the pressure and temperature during hydrate formation. While control unit is recording one pressure and one thermocouple, others are connected to a second data logger and laptop to record the data. This is actually a back-up to minimize the risk to lose the data. The data logger model is Elimko: E-680-08-2-0-00-1-0.
5.1.5 Cold room

One of the characteristics of hydrate formation experiments is cooling since hydrate forms at low temperatures. Cooling requirement is achieved by a cold room having dimensions of 3 x 3 x 2.5 m. Working range of the room are -5 °C - +10 °C.

5.2 Experimental procedure

Pure methane (99.995 % - Hat Grup Company, Kocaeli-Turkey) and methane – propane mixture (95 % methane and 5 % propane – Hat Grup Company, Kocaeli-Turkey) were used to form hydrates either at high-pressure steel reactor or medium-pressure PMMA reactor. Distilled water is the liquid phase to form hydrate. In addition, the hydrate formation kinetics of the aqueous phases containing amino acids was studied experimentally. In that respect, depending on the type of gas and aqueous phase different experimental procedures were applied.

5.2.1 High-pressure steel reactor – methane

The following procedure has been applied during the course of 24 experiments where high-pressure steel reactor was used to form methane hydrate with distilled water.

- Turn on cooling unit to adjust the room temperature to 10 °C.
- Put distilled water (2.65 liter for single impeller or 3.8 liter for dual impeller experiments) while the top lid of the reactor is open.
- Insert the selected baffle and adjust the height of it with respect to gas – liquid interface.
- Connect the selected impeller(s) to the shaft then close the top lid and make necessary connections for data recording and gas injection. Start data recording.
- Inject methane into reactor via gas injection valve and adjust the reactor pressure to 46 ± 0.2 bar-g.
- Then, after closing the gas injection line set the cooling unit temperature to – 5 °C to start the cooling of cold room.
• Continuously observe the reactor pressure and temperature until reactor temperature is about $2 \pm 0.2$ °C.

• At this point reset the cooling unit temperature to 0 °C and start servo motor with a rotational speed of 500 RPM for a period of 10 hours.

• Hydrate formation generally starts within few minutes after the start of rotation. But, in some cases, depending on impeller – baffle configuration, it may take hours (induction time). Keeping this fact in mind, the reactor pressure and temperature trends are observed carefully. A change in the pressure decline rate (an increase in rate) and a sharp increase in temperature indicate the initiation of hydrate formation. Record this time and keep rotation 3 hours more, then stop rotation.

• Transfer the recorded data from two data logging units and release the pressure to prepare the system for the next experiment.

Figure 5.12 shows the pressure – temperature traverse during hydrate formation process with a reference line showing the methane hydrate equilibrium. Hydrate equilibrium line is obtained from CSMHYD (Research Center for Hydrates, Chemical Engineering Department, Colorado School of Mines). The decrease in pressure from initial condition to start of rotation is due to cooling and dissolution of gas in water. On the other, the change in pressure and temperature after rotation is due to formation of hydrate which is an exothermic reaction with consumption of gas into solid phase.
5.2.2 High-pressure steel reactor – methane propane mixture

Sixteen hydrate formation experiments (8 with single impellers, 8 with dual impellers) were carried out with the use of gas mixture to form hydrates. The experimental procedure of mixture gas experiments is almost the same of methane experiments except the differences given below.

- The first difference is the initial conditions at which the mixture gas was injected into the reactor. Since methane – propane mixture forms hydrate at a lower pressure compared to methane at the given temperature, the initial pressure was lowered from $46 \pm 0.2$ bar-g to $26 \pm 0.2$ bar-g at $13 \, ^\circC$. Therefore the first step of the experiment was adjusting the cold room temperature to $13 \, ^\circC$ by the help of cooling unit.

- The other difference was the temperature at which the rotation was started. It is known from literature that use of gas mixtures to form hydrates results with difference in fractionation of mixture components in gas phase and hydrate phase. This fractionation actually results with the change in equilibrium
conditions since one of the components of gas phase is spent more in hydrate formation than the other component. In order to test this phenomenon some of the gas mixture hydrates formation carried out at a higher temperature (8 °C) while the rest had the same temperature of methane experiments (2 °C). Figure 5.13 shows the experimental conditions of gas mixture hydrate formations.

- At the end of each hydrate formation experiment of gas mixture the composition of free gas was determined by taking gas samples in sampling tubes (Figure 5.14) aiming to quantify the fractionation of gas components. Gas composition analyses were carried out at Petroleum Research Center Gas Analysis Laboratory by using Agilent 6890 series GC (Figure 5.15).

Figure 5.13 Experimental conditions of gas mixture experiments
The last part of the study aims to see the effect of some selected amino acids on natural gas hydrate formation. In that respect, the following 5 different amino acids from EMD Milipore Co. were added to hydrate forming water at certain concentrations.
- L-Lysine monochloride,
- L-Serine,
- L-Histidine monohydrochloride monohydrate,
- L-Leucine and
- L-Alanine.

The initial pressure and the temperature for these experiments were 24 bar-g and 2 °C while the water in transparent reactor was 300 cm³. The experimental procedure was the same of methane and methane-propane hydrate formation experiments with the advantage of eye observation.
As mentioned in Chapter 5, pure methane and methane–propane mixture (95 % methane and 5 % propane) hydrates are formed either at high-pressure steel reactor or medium-pressure PMMA reactor. In addition, some amino acids are tested on their promotion potential for hydrate formation. Experimental procedure for those tests was already given in Chapter 5. This chapter is dedicated on the discussion of experimental findings of methane hydrate formation.

At first, the raw data of a selected test will be presented as the sample of all experimental raw data, and then the raw data of all other tests will be given in Appendix A.

Later, again the same set of data is utilized to describe how the experimental data is interpreted to study the kinetics of hydrate formation.

Then, results of pure methane hydrate formation experiments are discussed, in detail.

6.1 Presentation of raw data

Pressure and temperature within the hydrate formation reactor and the torques during rotation of impellers are the three parameters recorded during any hydrate formation test. Those raw data are presented in three figures:
1. Pressure and temperature vs. time (Figure 6.1)
2. Pressure and torque vs. time (Figure 6.2)
3. Pressure vs. time with a reference line of hydrate equilibrium of hydrate forming gas (Figure 6.3)

Figures 6.1, 6.2 and 6.3 are showing the experimental data of hydrate formation test with following conditions:

- Hydrate forming gas: Methane (CH4)
- Number of impeller: Single impeller (SI)
- Type of impeller: Pitched –Blade Turbine (PBT)
- Type of baffle: Full (FB)
- Rotational speed: 500 RPM (500)

Each experiment will have a coding based on those parameters. As an example, the coding of this experiment is **CH4-SI-PBT-FB**.

The whole raw data of a given hydrate formation experiment has three distinct intervals as indicated in Figure 6.1.

1. After preparing the system to run a hydrate formation test, cooling is started without rotating the impeller. Decrease in temperature as response of cooling causes a decrease in pressure based on real gas law as well as in the increase of gas solubility. This period ends when temperature reaches to the determined hydrate formation temperature.

2. The second interval is the period in which hydrate formation is achieved. In order to initiate the hydrate formation and keep it continuous, the impeller is rotated at a speed of 500 RPM. The duration of this interval is dependent on the INDUCTION TIME which is known as the starting time of hydrate formation. Figure 6.1 shows that INDUCTION TIME of **CH4-SI-PBT-FB** experiment is almost ZERO and hydrate formation started immediately after the start of rotation. A three-hour rotation after induction time is set a standard for this study. After initiating the hydrate formation, a steep pressure decline is observed as a response of losing the free gas into solid hydrate structure. Another observation
is a slight increase in temperature due to exothermic characteristic of hydrate formation.

3. Three hours after INDUCTION TIME, rotation and cooling are stopped and the system is let to warm up. A longer waiting under these conditions will end of dissociation of hydrate. Since the main focus of this study is to determine the kinetics of hydrate formation, this period is generally kept short. Therefore, many of experiments ended before having a full cycle of hydrate formation – dissociation.

Figure 6.2 shows the pressure – torque data of experiment CH4-SI-PBT-FB. Measured torque (N/m) values will be utilized to calculate the overall power consumption during hydrate formation.

The last graph drawn from raw data is the pressure vs. temperature graph (Figure 6.3). The hydrate equilibrium line of hydrate forming gas (methane for CH4-SI-PBT-FB) is drawn as a reference to indicate the position of any pressure – temperature pair during experiment. The hydrate equilibrium line of hydrate forming gas/water mixture is obtained from CSMHYD (Sloan, 1990). As indicated in Figure 6.3 the initial condition of experiment is outside the hydrate formation region. Red arrows on the figure show the direction of pressure – temperature change by time. As cooling progresses, pressure – temperature pairs come closer to equilibrium line and at some point it crosses the hydrate equilibrium line. Further cooling without rotation makes the system temperature far inside the hydrate formation region. The difference between the hydrate equilibrium temperature at experimental pressure and experimental temperature is known as SUB-COOLING (black arrow line in the figure). The higher the SUB-COOLING the stronger the driving forces to initiate the hydrate formation. In order to have comparable kinetic data a fixed SUB-COOLING is applied throughout this study.

As hydrate formation progresses, pressure decreases and a slight increase in temperature is observed. The final step is letting the system to warm up after stopping the rotation and cooling to allow hydrate dissociation.
Figure 6.1 Pressure – temperature vs. time graph of hydrate formation experiment

Figure 6.2 Pressure vs. torque graph of hydrate formation experiment
6.2 Interpretation of experimental data

6.2.1 Gas consumption rate

The main objective of this study is to investigate the effect of different impeller – baffle configurations on hydrate formation kinetics. Therefore, a tool must be devised to extract the kinetic data from raw experimental data. Application of real gas law \((PV = \text{n}RT)\) for each data point with known pressure, temperature and free gas volume gives the change in number of moles of free gas with time. The gas compressibility factor of the real gas law \(Z\) is estimated by using Lee and Kesler’s (1975) compressibility factor expression. A sample plot of change in free gas number of moles is given in Figure 6.4 for CH4-SI-PBT-FB.
Figure 6.5 is plotted with the same data of Figure 6.4 but covering only hydrate formation period. A third-order polynomial fit of experimental data result with Equation 6.1.

\[ n = 1.0295 \times 10^{-15} t^3 + 1.4283 \times 10^{-11} t^2 - 1.3373 \times 10^{-7} t + 1.3441 \times 10^{-2} \]  
(Eq. 6.1)

where:

\[ n = \text{Number of moles of free gas, lb-mol} \]
\[ t = \text{Time, sec} \]

The derivative of Equation 6.1 results with the gas consumption rate (Equation 6.2) which can be considered as the hydrate formation rate.

\[ \frac{dn}{dt} = 3 \times 1.0295 \times 10^{-15} t^2 + 2 \times 1.4283 \times 10^{-11} t - 1.3373 \times 10^{-7} \]  
(Eq. 6.2)

where:

\[ \frac{dn}{dt} = \text{Gas consumption rate, lb-mol/sec} \]
\[ t = \text{Time, sec} \]

Comparison of gas consumption rates of different experiments will be done by utilizing gas consumption rate equations (Equation 6.2 is an example) with four different time values, namely 1, 600, 1200 and 1800 seconds. Table 6.1 presents the gas consumption rates of experiment CH4-SI-PBT-FB, as an example.

<table>

</tr>
</tbody>
</table>
Figure 6.4 Calculated number of moles of free gas during hydrate formation

\[ PV = znRT \]

Figure 6.5 Gas consumption rate equation
6.2.2 Overall power consumption

Power consumption was calculated based on the torque measured every second based on the following equation:

\[ P_c = T_q \times 2\pi N \]  \hspace{1cm} (Eq. 6.3)

where \( T_q \) is the Torque in N-m and \( N \) is the rotational speed in rps and power consumption is in Watt.

The power consumption at every second over the duration of hydrate formation for each experiment was summed to obtain overall power consumption during the experiment. The duration for the calculation of overall power consumption is the sum of the induction time of a given experiment and the hydrate formation duration of the experiment with shortest duration.

6.2.3 Hydrate yield

The percent of water conversion to hydrate or hydrate yield is defined from the information of hydrate growth rate obtained from gas uptake and the experimental conditions using Equation 6.4:

\[
\text{Conversion of water to hydrate (mol\%) = } \frac{\Delta n_{H_2O} \times \text{Hydration Number}}{n_{H_2O}} \times 100 \] \hspace{1cm} (Eq. 6.4)

where

\[ \Delta n_{H_2O} = n_i - n_{end} \]

\( n_i \) = moles of free gas when hydrate formation starts or moles of free gas at induction time,

\( n_{end} \) = moles at free gas at the end of hydrate formation

\( n_{H_2O} \) = moles of water in the reactor
The hydration number is the number of water molecules required per guest methane molecule which is taken as 6.1 from literature [214].

6.2.4 Hydrate Productivity

Hydrate productivity is defined by the formula

\[ NR_{30} = \frac{R_{30}}{V_{\text{water}}} \text{ (mol lt}^{-1} \text{s}^{-1}) \]  

(Eq. 6.5)

where

\( V_{\text{water}} \) is the volume of water (lt) in the reactor,

\( R_{30} \) is the rate of hydrate growth (mol s\(^{-1}\)) calculated by fitting the gas uptake due to hydrate growth versus time for the first 30 minutes after the induction time.

6.3 Kinetic Analysis of methane hydrate formation

Twenty-four experiments with different impeller – baffle configurations given in Figure 6.6 were conducted to determine their effect on kinetics and efficiency of methane hydrate formation.

The twenty-four experiments were divided in eight experiments with single impellers (SI) and sixteen experiments with dual impellers. The single eight experiments conducted with two different impellers: up-pumping pitched blade turbine (PBTU) which generates mixed flow and with Rushton turbine (RT) which generates radial flow. The sixteen experiments of dual impellers were divided in dual impellers (DI) when the impellers are the same and in dual mixed impellers (DMI) when the two types of impellers are mixed. Hence the experiments with dual impellers conducted with the four possible combinations such as PBTU-PBTU, RT-RT, PBTU-RT and RT-PBTU where the first impeller named is the one that was positioned lower on the shaft. Each impeller combinations are tested with four baffle types as full baffle (FB), half baffle (HB), surface baffle (SB) and no baffle (NB).
As referred before in this chapter, the recorded data during hydrate formation are pressure, temperature and torque during rotation, at every second. By the use of temperature and pressure with the assistance of Lee and Kesler’s (1975) compressibility factor expression, the number of moles of free gas in the reactor (n) at the time of interest during hydrate formation and z compressibility factor are calculated since we also know the volume for each experiment. The graphs of pressure and temperature vs time, pressure and torque vs time and pressure vs time in methane hydrate equilibrium...
curve for all eight single experiments are presented in Appendix A, (Figures A.1 to A.4 are for PBTU and Figures A.5 to A.8 are for RT experiments).

Table 6.2 summarizes the results of single impeller (SI) experiments. Stirring is started at the same pressure and temperature conditions (42.5 bar-g and 2 °C) in all experiments. Since the hydrate equilibrium temperature (T_{eq}) of pure methane is 10.5 °C at 42.5 bar-g, the driving force at the start of stirring is 8.5 °C for all experiments.

Analysis of the raw data of PBTU experiments indicate different induction times depending on the type of baffle used. The shortest induction time was 3 minutes with full baffles (FB) while it was 50 minutes and 42 minutes for half (HB) and surface baffles (SB), respectively. On the other hand, it took 10 hours and 15 minutes to observe the start of hydrate formation in no baffles (NB) case. After having such a long induction time for PBTU with NB, this test was repeated and an induction time of 12 hours and 34 minutes was obtained.

The baffles provide axial flow and eliminate the central vortex in a stirred tank. When full baffles are used, it is expected to observe the axial motion of the reactor contents beginning from the bottom of the tank. When shortened baffles such as half and surface baffles are used, however, the tangential flow would be dominant at the bottom of the tank. The axial motion would begin where or whereabouts of the start of the baffles. When there are no baffles in the system, the tangential flow is dominant everywhere, and a central vortex would form. The central vortex could be useful in incorporating gas if the vortex reaches the impeller; however, excessive entrance of the gas would have a significant effect on the hydrodynamics in the tank and the gas entrance through the vortex can become an undesired situation. Based on these, it is seen here that when full baffles are used, there is sufficient gas entrance to the system and the axial flow provided by the baffles allow for the induction to begin much faster. As the baffles become shorter, the possible disconnect between the bottom of the tank and the top where baffles are present do not allow for such efficient gas-liquid contact, and
induction time increases. When no baffles are used, the hydrodynamics completely change, in no favor of the induction time, and a substantial increase is seen.

In all experiments, an increase in the temperature of the system is observed with the initiation of hydrate since the reaction is exothermic. This effect is more pronounced in the experiments with no baffles, indicating a serious heat transfer limitation (Appendix A and Figure A.4).

The results of induction time for RT experiments are closer to each other, but they follow a similar trend. In the full baffles (FB) experiment, the induction time is 4 minutes while it is 25 and 23 minutes in the half (HB) and surface (SB) baffles experiments, respectively. In no baffles (NB) experiment the induction time is 53 minutes and it is the highest value. It is seen that when half and surface baffles are used and no baffles inserted, with the RT impeller hydrates begin to be formed more quickly compared to PBTU. This difference may result in from the different flow patterns the two impellers generate. PBTU is a mixed flow impeller which gives both radial and axial flow and RT is a radial impeller. RT is known to be a shear intensive impeller. This means that whether there are baffles or not, RT is better in producing smaller gas bubbles that enter the reactor either through the surface or through the hollow shaft and as a result, from the sparger. The smaller bubbles allow for the induction time to decrease. It should, however, be noted that RT is not advantageous compared to the PBTU when full baffles are used. This is probably because the mixed flow generated by the PBTU, combined with full baffles allows for better interaction between the gas and the liquid phases, even though the bubbles generated are possibly larger compared to the RT. This also shows that the combination of the type of the impeller and baffle configuration is important in the decision of tank interiors for hydrate production.

Although it was aimed to continue hydrate formation at least 3 hours after the initiation of hydrate formation, this was not achieved for all single impeller experiments. Column 6 in Table 6.2 reports the duration of hydrate formation for single impeller experiments. It is seen that it was possible to form hydrates as long as 3 hours for all PBTU
experiments but none of the RT experiments lasted 3 hours although stirring continued more than 3 hours after initiation of hydrate formation. The main reason of shortened hydrate formation duration in RT experiments is the higher increase in temperature subsequent to hydrate formation compared to PBTU experiments (Appendix A, Figures A.1 to A.8). This phenomenon will be discussed further in the following sections when the hydrate formation rate data is presented.

The change in the number of moles of free gas after the initiation of hydrate formation was used to calculate the rate of hydrate formation at four different times (1 second, 10, 20 and 30 minutes). The graphs of number of moles of free gas vs time and gas consumption rate equations for all single impeller experiments for each configuration are presented in Appendix B (Figures B.1 to B.16).

Figure 6.7 presents the hydrate formation rates of single impeller experiments. The following results are deduced from the analysis of Figure 6.7.

1. The initial hydrate formation rate (rate at 1 sec) of any experiment is always the highest for the given experiment and there exists continuous decrease in hydrate formation rate by time. The possible reasons of the decline in hydrate formation rate are:
   a) Although hydrate is initially started to form at the gas – water interface and tried to be removed from the interface by mixing, some of the hydrate may stay at the interface. This may result with the restriction of mass transfer between phases,
   b) As mentioned earlier hydrate formation is an exothermic process. If the heat of hydrate formation is not removed efficiently from the reactor an increase in reactor temperature may occur. An increase in reactor temperature result with reduction in driving force.

2. Hydrate formation rates of RT experiments are always higher than hydrate formation rates of PBTU experiments, for all types of baffles.
3. Although the initial hydrate formation rates of RT experiments are higher compared to PBTU experiments, the hydrate formation rates of RT experiments decrease faster than PBTU experiments. Reasons mentioned in 1a and 1b would be the responsible for this phenomenon. The higher hydrate formation rate results with more hydrate formation in short period of time causing higher restriction of mass transfer between phases. On the other hand, there is little decline in hydrate formation rate with time for PBTU experiments which started with relatively low hydrate formation rate. This difference actually created the shortening of the duration of hydrate formation in RT experiments.

* Driving force = $T_{exp} - T_{eq}$
Hydrate growth rate for the first 30 minutes divided by the volume of water in the system is defined as hydrate productivity (Equation 6.5). The results of hydrate productivity of single impeller experiments are presented in Figure 6.8.

Hydrate productivity has an analogy with the rate of hydrate formation. RT experiments have higher hydrate productivity compared to PBTU experiments.

Conversion of water into hydrate (hydrate yield) is calculated based on the hydration number (6.1) and the change in the number of moles of gas during hydrate formation (Equation 6.4). The results are presented at the last column of Table 6.2. It is clear from the hydrate yield values that the amount of water that is converted to hydrates is very small. The main reason of this is the excessive water used in experiments. In a batch type experiment with excessive water, the hydrate formation is hindered by time in response to exothermic nature of hydrate formation if the heat of formation is not fully
removed from the system. In addition, the hydrate layer at the gas – water interface would have an obstructive effect to decrease the mass transfer between hydrate forming phases. These observations actually indicate some of the drawbacks of stirred tank reactors in hydrate formation.

*Figure 6.8* Hydrate productivity of single impeller experiments

Overall power consumption during hydrate formation is the last outcome obtained from experimental data. Equation 6.3 is utilized to calculate the power consumption at every second and the summation of all these gave the overall power consumption. The duration for the calculation of overall power consumption is the sum of the induction time of a given experiment and the hydrate formation duration of the experiment with shortest duration. The experiment with Ruston turbine (RT) and no baffle (NB) had the shortest hydrate formation duration among this group experiments as 1 hour and 50 minutes. *Figure 6.9* shows the overall power consumptions of all single impeller experiments.
It is obvious from Figure 6.9 that hydrate formation experiment with PBT impeller and no baffle case is an outlier owing to the fact that this experiment had a very long induction time (10 hours and 15 minutes). This long induction with no hydrate production increased the overall power consumption of this particular experiment.

Apart from PBTU impeller – no baffle case, RT experiments have higher overall power consumptions compared to PBTU experiments although RT experiments produced hydrate for shorter periods than PBTU experiments. This difference comes from the higher torque values measured in RT experiments than PBTU experiments. The RT impeller has higher power number; therefore, higher torque requirement. Figure 6.10 plots the torque values of all single impeller experiments after the initiation of stirring. It is seen that all PBTU experiments generally have torque values smaller than 0.9 N-m while RT experiments have higher than 0.9 N-m, even very high at the start of stirring reaching to 1.9 N-m.

**Figure 6.9** Overall power consumption of single impeller experiments
In the second group of experiments with pure methane dual impellers of the same type (PBT-PBT of RT-RT) were used. Table 6.3 gives the summary of results for dual impeller experiments. Pressure and temperature conditions at the starting time of stirring are the same of single impeller experiments (42.5 bar-g, 2 °C). The graphs of pressure and temperature vs time, pressure and torque vs time and pressure vs time in methane hydrate equilibrium curve for all eight dual impeller experiments are presented in Appendix A, (Figures A.9 to A.12 are for PBTU/PBTU and Figures A.13 to A.16 are for RT/RT experiments).

Analysis of the raw data of PBTU/PBTU and RT/RT dual impeller experiments for induction time shows the same trend of single impeller experiments. The shortest induction time are with full baffles (FB) (3 minutes for PBTU/PBTU and 4 minutes for RT/RT). Then induction times are increasing in the same order half baffles (HB), surface baffles (SB) and no baffles cases (NB). Therefore, the discussion made for the effect of
baffle types on the induction time of single impeller experiments is also valid for dual impeller experiments.

Column 6 in Table 6.3 lists the duration of hydrate formation for dual impeller experiments. It is seen that it was possible to form hydrate as long as 3 hours for only two experiments and others last shorter than 3 hours of hydrate formation although stirring continued more than 3 hours after initiation of hydrate formation. Comparison of duration of hydrate formation for single and dual impellers indicates that use of dual impellers generally shortened the duration of hydrate formation (Table 6.4).

Figure 6.11 shows the overall power consumption during hydrate formation with dual impellers. In order to find the duration for the calculation of overall power consumption of a given experiment, the shortest hydrate formation duration of dual Rushton turbine (RT/RT) with full baffle (FB) (22 minutes) was added to the induction time of the particular experiment. It is clear from Figure 6.11, two experiments with very short induction times had relatively low overall power consumption. On the other hand, the longer the induction time resulted with higher overall power consumptions. This clearly shows the importance of shorter induction time to reduce the overall power consumption. On the other hand, although PBT/PBT-HB experiment had shorter induction time compared to PBT/PBT-SB and PBT/PBT-NB experiments, its overall power consumption higher. PBT/PBT-HB experiment had the highest torque values (Figure 6.12) recorded among this group of experiments causing an increase in overall power consumption.

As in the case of single impeller experiments, the change in the number of moles of free gas after the initiation of hydrate formation was used to calculate the rate of hydrate formation at four different times (1 second, 10, 20 and 30 minutes). The graphs of number of moles of free gas vs time and gas consumption rate equations for all single impeller experiments for each configuration are presented in Appendix B (Figures B.17 to B.32).
Figure 6.13 presents the hydrate formation rates of dual impeller experiments. The following results are obtained from the analysis of Figure 6.13.

1. The initial hydrate formation rate (rate at 1 sec) of any experiment is always the highest for the given experiment and there exists continuous decrease in hydrate formation rate by time. The same reasoning of single impeller experiments is valid for dual impeller case.

2. Hydrate formation rates of RT/RT experiments are always higher than hydrate formation rates of PBTU/PBTU experiments, for all types of baffles.

3. On the other hand, although the initial hydrate formation rates of RT/RT experiments are higher compared to PBTU/PBTU experiments, the hydrate formation rates of RT/RT experiments decrease faster than PBTU/PBTU experiments. Reasons mentioned in 1 would be the responsible for this phenomenon. The higher hydrate formation rate results with more hydrate formation in short period of time causing higher restriction of mass transfer between phases. On the other hand, there is little decline in hydrate formation rate with time for PBTU/PBTU experiments which started with relatively low hydrate formation rate. This difference actually created the shortening of the duration of hydrate formation in RT/RT experiments.

Regarding the hydrate yield (the last column of Table 6.4), the percentage of water converted to hydrate gets smaller in dual impeller experiments compared to single impeller experiments. This is an expected result since the amount of water was increased in dual impeller experiments to place the upper impeller in liquid water.

Figure 6.12 Recorded torque values of single impeller experiments

Figure 6.13 Rate of hydrate formation of PBT/PBT and RT/RT dual impellers for time period of 1, 600, 1200 and 1800 seconds
The third and the last group of experiments are the ones with pure methane are dual mixed impellers of different types (PBT/RT of RT/PBT). In the description of any dual mixed experiment the impeller written first is attached to the shaft at a lower position (close to sparger) while the second one is attached to the shaft closer to the gas-liquid interface.

Table 6.5 gives the summary of results for dual mixed impeller experiments. Pressure and temperature conditions at the starting time of stirring are the same of the previous experiments (42.5 bar-g, 2 °C). The graphs of pressure and temperature vs time, pressure and torque vs time and pressure vs time in methane hydrate equilibrium curve for all eight dual impeller experiments are presented in Appendix A (Figures A.17 to A.20 are for PBTU/RT and Figures A.21 to A.24 are for RT/PBTU experiments).

Analysis of the raw data of dual mixed impeller experiments for induction time shows the same trend of single and dual impeller experiments. The shortest induction time are with full baffles (FB) (2 minutes for PBTU/RT and 3 minutes for RT/PBTU). Then induction times are increasing in the same order half baffles (HB), surface baffles (SB) and no baffles cases (NB). Therefore, the discussion made for the effect of baffle types on the induction time of single and dual impeller experiments is also valid for dual mixed impeller experiments.

Column 6 in Table 6.5 lists the duration of hydrate formation for dual impeller experiments. It is seen that it was possible to form hydrate in half of the experiments as long as 3 hours and others lasted shorter than 3 hours of hydrate formation although stirring continued more than 3 hours after initiation of hydrate formation. There is no general trend for the duration of hydrate formation for dual mixed impeller experiments.

The overall power consumption during hydrate formation with dual-mixed impellers is given in Figure 6.14. The duration for the calculation of overall power consumption of a given experiment was obtained by the summation of the induction time of the particular experiment and hydrate formation duration of the experiment having shortest hydrate
formation period (dual-mixed Pitched blade turbine / Rushton turbine (PBT/RT) with full baffle (FB) (24 minutes)). It is clear from Figure 6.14, two experiments with very short induction times had relatively low overall power consumption. On the other hand, the experiments having induction times closer to or longer than an hour had higher overall power consumptions. This clearly shows the importance of shorter induction time to reduce the overall power consumption. A similar observation is made from Figure 6.15 by comparing the measured torque values of dual-mixed impeller experiments. Two experiments of pitched blade turbine / Rushton turbine (PBT/RT) with surface baffle (SB) and no baffle (NB) had the lowest torque values but because of their longer induction times (about two hours) they had the highest overall power consumption.

As in the case of single and dual impeller experiments, the change in the number of moles of free gas after the initiation of hydrate formation was used to calculate the rate of hydrate formation at four different times (1 second, 10, 20 and 30 minutes). The graphs of number of moles of free gas vs time and gas consumption rate equations for all dual mixed impeller experiments for each configuration are presented in Appendix B (Figures B.33 to B.48).

Figure 6.16 presents the hydrate formation rates of dual mixed impeller experiments. Almost all combinations of dual mixed impeller and baffles start with relatively high hydrate formation rates but decrease about the half of the initial rate in a short period of time. This observation indicates that dual impeller arrangement is suitable for hydrate formation but the higher initial rate of hydrate formation limits the mass transfer between phases because of the batch type operation. The highest gas consumption rate is obtained from PBT/RT impellers and FB baffles.

*Driving force = $T_{\text{exp}} - T_{\text{eq}}$
**Figure 6.14** Overall power consumption of dual-mixed impeller experiments

**Figure 6.15** Recorded torque values of dual-mixed impeller experiments
Two important parameters dictating the suitability of a given impeller – baffle configuration on natural gas hydrate formation are induction time and the rate of hydrate formation. Although experimental results indicate a regular change in the induction time with the type of baffle (shortest with full baffle and in an increasing order with half, surface and no baffle) it is not possible to assign a numerical value because of its stochastic nature. On the other hand, experimental results indicated that it is possible to define the hydrate formation rate with a third order polynomial. Experimental data of 24 methane hydrate formation experiments fit to a 3rd order polynomial with correlation coefficients ($R^2$) close to 1. But, there is still a question about the repeatability of the tests. Repeatability is defined as the closeness of agreement between independent test results, obtained with the same method, on the same test material, in the same

**Figure 6.16** Rate of hydrate formation of dual mixed impellers for time period of 1, 600, 1200 and 1800 seconds.
laboratory, by the same operator, and using the same equipment within short intervals of time. In order to check the repeatability of hydrate formation experiments of this study three tests were repeated. Then their induction times and hydrate formation rates were compared. Those tests were chosen as one test for each of the single, dual and dual mixed impeller arrangements. Table 6.6 lists the gas consumption rates and induction times for comparison which are also shown as bar charts in Figures 6.17 to 6.19.

Regarding the induction time, although it has a stochastic nature the results show similarity. On the other hand, gas consumption rates of repeatability tests are quite close to each other. Gas consumption rates of experiments with single impeller and no baffle almost the same (Figure 6.17). Repeatability tests with dual and dual mixed impellers show some differences in gas consumption rates (Figure 6.18 and 6.19). Gas consumption rates of two repeatability tests with dual mixed impeller with full baffle have small differences but exhibit the same trend. Although the numerical values differ slightly the behavioral change with time is considered as the sign of repeatability. The last pair for repeatability are the experiments with dual Rushton turbine impellers with full baffle. This arrangement has the highest gas consumption rates among all other impeller – baffle configurations. Figure 6.19 shows that both repeatability tests resulted with higher gas consumption rates, again showing the sign of repeatability.

CHAPTER 7

RESULTS AND DISCUSSION OF METHANE – PROPANE MIXTURE HYDRATE FORMATION

As far as it concerns, hydrate formation experiments of methane – propane mixture (95% methane-5% propane) experimental data is interpreted as in methane hydrate experiments with some additional steps to take into account the fractionation of the gas components in the gas and hydrate phases. Chromatographic analysis of free gas at the end of hydrate formation process was carried out to determine the partition of methane and propane in free gas and hydrate structure. Split fraction of methane and propane and separation factor of propane are calculated based on kinetic analysis of experimental data and chromatographic analysis of gas sample taken at the end of hydrate formation [215].

**Split fraction**

Split fraction (S.Fr) given in equations 7.1 and 7.2 are used to quantify the partition of hydrate forming gases in free gas and solid hydrate phases.

The split fraction of methane is calculated as follows:

\[
S.\text{Fr}_{\text{CH}_4} = \frac{n^H_{\text{CH}_4}}{n^\text{Feed}_{\text{CH}_4}}
\]  

(Eq. 7.1)
where \( n_{\text{CH}_4}^{\text{Feed}} \) is the number of moles of methane in feed gas and \( n_{\text{CH}_4}^H \) is the number of moles of methane in hydrate phase at the end of the experiment.

Similarly, the split fraction (S.Fr.) of propane is calculated as follows:

\[
\text{S.Fr.}_\text{C}_3\text{H}_8 = \frac{n_{\text{C}_3\text{H}_8}^H}{n_{\text{C}_3\text{H}_8}^{\text{Feed}}} \tag{Eq. 7.2}
\]

where \( n_{\text{C}_3\text{H}_8}^{\text{Feed}} \) is the number of moles of propane in feed gas and \( n_{\text{C}_3\text{H}_8}^H \) is the number of moles of propane in hydrate phase at the end of the experiment.

**Separation Factor**

Natural gas hydrates are frequently used to separate gas components of given gas mixtures owing to the fact that those separated components either consumed more into the hydrate structure than the other components of the mixture, or they do not go into the hydrate structure at all. In this study, the mixture that is used to form hydrates are both hydrate formers but it is known from literature that propane is consumed more compared to methane. Since the studied gas is rich in methane, it was decided to analyze how propane is separated from the mixture depending on the experimental conditions. Equation 7.3 is utilized to calculate the separation factor of propane (S.F\text{C}_3\text{H}_8) [215].

\[
\text{S.F}\text{C}_3\text{H}_8 = \frac{n_{\text{C}_3\text{H}_8}^H \times n_{\text{C}_3\text{H}_8}^{\text{gas}}}{n_{\text{CH}_4}^H \times n_{\text{C}_3\text{H}_8}^{\text{gas}}} \tag{Eq. 7.3}
\]

where \( n_{\text{CH}_4}^{\text{gas}} \) is the number of moles of methane in the gas phase at the end of hydrate formation, \( n_{\text{C}_3\text{H}_8}^{\text{gas}} \) is the number of moles of propane in the gas phase at the end of the hydrate formation, \( n_{\text{C}_3\text{H}_8}^H \) is the number of moles of propane in the hydrate phase.

In total, 24 hydrate formation experiments were conducted with 95 % methane 5% propane mixture (Figure 7.1). The driving force of 8 experiments out of 24 was the same as pure methane experiments (8.5 °C). Since methane – propane mixtures form hydrate at relatively low pressure than pure methane for a given temperature, the pressure at the
starting time of stirring was chosen as 26.5 bar-g which corresponds to the hydrate equilibrium temperature of 17 °C for 95 % methane – 5 % propane mixture. After completing these 8 experiments, it was found that the experimental conditions were not suitable for longer period of hydrate formation. The reason for shorter duration of hydrate formation was the change in hydrate equilibrium curve as most of the propane was consumed in hydrate formation and remaining free gas became richer in methane. The more the methane in free gas the higher the hydrate equilibrium pressure. On the other hand, the reactor pressure decreases by hydrate formation. As a result, the driving force gets smaller by time and at some point hydrate formation stops. After realizing this fact, the remaining 16 experiments were carried out at 2 °C which was the temperature of methane hydrate experiments. Another change in this group of experiments was the pressure at the start of stirring. It was kept at 24.5 bar-g.

1. **Figure 7.1** Repeatability Diagram showing the impeller – baffle configurations of 24 methane -propane mixture hydrate experiments
Another important difference from pure methane experiments was the sampling of free gas at the end of each experiment. Gas samples were analyzed by gas chromatography to determine the degree of fractionation of methane and propane between free gas and solid hydrate phases.

Another parameter for grouping of methane – propane mixture experiments is the type of impeller. Single impellers were used in 16 experiments and dual impellers were used in the remaining 8 experiments. Half of the single impeller experiments were realized at 8.5 °C and the other half at 2 °C.

Interpretation of experimental data is the same as the interpretation of methane experiments. Therefore, the graphs of pressure and temperature vs time, pressure and torque vs time and pressure vs time in methane-propane hydrate equilibrium curve were drawn and presented in Appendix A, (Figure A.25 to A.32 for PBTU and RT experiments with experimental temperature of 8.5 °C and Figure A.33 to A.40 for PBTU and RT experiments with experimental temperature of 2 °C).

Table 7.1 summarizes the results of single impeller, methane – propane mixture experiments. The following findings are drawn from Table 7.1:

- Except in one experiment (Rushton turbine – half baffle), hydrate formation started almost immediately after the start of stirring (very short induction times).
- Duration of hydrate formation was always shorter than 3 hours in experiments with higher experimental temperature (8.5 °C). This is attributed to the lower driving force as explained earlier. Furthermore, experiments with RT last shorter compared to experiments with PBTU.
- Experiments with lower experimental temperature (2 °C) and PBTU type impeller had hydrate formation durations longer than 3 hours. But the change in impeller type from PBTU to RT resulted with shortening of hydrate formation duration.
- Split fraction values of methane are relatively low (between 0.040 and 0.133) indicating that a higher percentage of methane in the original gas still remains in free gas phase. On the other hand, the split fraction of methane values are high in case of higher driving force (Figure 7.2).
- Split fraction values of propane are much higher compared to the split fraction values of methane, as expected. Again, higher driving force resulted with higher split fraction for propane (Figure 7.3) as high as 0.889 (almost 90% of propane consumed for hydrate production).
- Final parameter to be discussed in Table 7.1 is the separation factor of propane. Depending on experimental conditions, propane separated from the mixture with a factor between 8 to 64 compared to methane. The higher the driving force the better the separation of propane from the mixture (Figure 7.4).

Discussion on split fractions and separation factor of propane clearly indicates the change in the composition of hydrate forming gas as hydrate formation progresses. In order quantify this phenomenon, chromatographic analysis of gas samples after hydrate formation are plotted on Figures 7.5 and 7.6. Arithmetic average of free gas compositions at the end of single impeller experiments with lower driving force is 97.08% methane and 2.92% propane (Figure 7.5) indicating an increase in methane mole percentage compared to feed gas composition. Figure 7.7 shows the experimental pressure – temperature data with hydrate equilibrium lines of feed gas and free gas after hydrate formation. As seen, hydrate formation line is shifting closer to experimental conditions. The consequence is a reduced driving force for hydrate formation. Same observation is valid for experiments with higher driving forces but higher consumption of propane, ending up with an average free gas composition of 99.24% of methane and 0.76% of propane (Figure 7.6). Again, the experimental condition after hydrate formation is very close to the hydrate equilibrium line of free gas sampled at this condition (Figure 7.8).

Figure 7.2 Split fraction of methane of single impeller mixture hydrate experiments

Figure 7.3 Split fraction of propane of single impeller mixture hydrate experiments
**Figure 7.4** Separation factor of propane of single impeller mixture hydrate experiments

**Figure 7.5** Composition of feed gas and free gas at the end of single impeller experiments (lower driving force)
Figure 7.6 Composition of feed gas and free gas at the end of single impeller experiments (higher driving force)

Figure 7.7 Pressure – temperature diagram of mixture gas of SI-RT-FB (lower driving force)
Figure 7.8 Pressure – temperature diagram of mixture gas of SI-RT-FB (higher driving force)

Rate of hydrate formation charts of mixture gas with single impeller for lower and higher driving forces are presented in Figures 7.9 and 7.10, respectively. The graphs of free gas vs time for all single impeller experiments and gas consumption rate equations are presented in Appendix B (Figures B.49 to B.68 for lower driving force and Figures B.69 to B.90 for higher driving force).

The common characteristics of hydrate formation rate changes is the continuous decline of rate by time for a given experiment. Initial hydrate formation rates for RT experiments generally higher than PBTU experiments for the same type of baffle (Figures 7.9 and 7.10). On the other hand, the decline rate of hydrate formation is higher for RT compared to PBTU.
Figure 7.9 Rate of hydrate formation of mixture gas with single impeller and lower driving force (experimental temperature 8.5 °C)

Figure 7.10 Rate of hydrate formation of mixture gas with single impeller and higher driving force (experimental temperature 2 °C)
Table 7.2 summarizes the results of dual impeller, methane – propane mixture experiments. Eight experiments realized with dual impellers at 2 °C experimental temperature. The following findings are drawn from Table 7.1:

- In all dual impeller experiments with mixture gas, hydrate formation started almost immediately after the start of stirring (2 minutes of induction times).
- Duration of hydrate formation was always shorter than 3 hours in all experiments. The effect of baffles for a given impeller type is opposite for dual impellers of PBTU and RT. The duration of hydrate formation decreases in the order of FB, HB, SB and NB for PBTU/PBTU but in opposite direction for RT/RT.
- Split fraction values of methane are again relatively low (between 0.115 and 0.223) but higher in dual impeller experiments compared to single impeller ones (Figure 7.11).
- Split fraction values of propane are much higher compared to the split fraction values of methane, as expected. Again, higher split fractions of propane were observed in dual impeller experiments compared to single impeller experiments (Figure 7.12).
- Depending on experimental conditions, propane separated from the mixture with a factor between 22 to 72 compared to methane. Comparison of separation factors of propane for single and dual impeller experiments did not show a distinct trend (Figure 7.13).

Rate of hydrate formation of mixture by using dual impellers are presented in Figure 7.14. Again, the results are given for 1, 600, 1200 and 1800 seconds. The graphs of free gas vs time for all dual impeller experiments and gas consumption rate equations are presented in Appendix B (Figures B.91 to B.113). The initial hydrate formation of RT/RT experiments with full, half and surface baffles were comparatively high among all other hydrate formation experiments of this study. But, there exists very sharp decline in hydrate formation rate within first 600 seconds. The main reason of such a sharp decline is attributed to the higher amount of hydrate formation which could restrict the
mass transfer between gas and liquid phases if the solid hydrate is not removed efficiently from the gas – liquid interface. Increase in temperature due to exothermic nature of hydrate formation, change in the composition of hydrate forming gas due to different partition of components in free gas and hydrate phases are other reasons to be mentioned.

RESULTS AND DISCUSSION OF METHANE – PROPAINE MIXTURE HYDRATE FORMATION WITH AMINO ACIDS

Previous chapters were dedicated to discuss the effect of impeller – baffle configurations on pure methane and methane – propane gas mixture hydrates formation. Distilled water was used as the aqueous phase while forming hydrates from those gas phases. It is a common application to use some chemicals to change the hydrate equilibrium conditions and/or kinetics of hydrate formation. There are three different classes of chemical inhibitors to prevent hydrate formation. Thermodynamic inhibitors aim to change the hydrate equilibrium conditions of a given system, kinetic inhibitors slow down the hydrate formation process and anti-agglomerants prevent the coagulation of already formed hydrate particles. On the other hand, promoters can also be used to increase the hydrate formation rate.

Recently amino acids have been introduced as hydrate promoters and/or inhibitors. In our study five different amino acids were examined and compared about their effectiveness on induction time, hydrate formation rate and overall power consumption. Table 8.1 gives some of the properties of amino acids used in this study.

In total, six hydrate formation experiments of mixture gas (95% methane and 5% propane) have been conducted by using the transparent reactor introduced in Chapter 5.1.1. Table 5.2 gives the dimensions of transparent reactor. An up-pumping pitch blade turbine (PBTU) - full baffle (FB) configuration was used in all experiments.
Experimental procedure of these tests are given in Chapter 5.2.3. It should be noted that the rotation started when the temperature was 2°C and the pressure was 24 bars. One of the six experiments was carried out by using distilled water as base experiment to study the effect of aqueous solutions of 1 weight percent of amino acids.

Figure 8.1 presents the induction time of methane-propane hydrate formation of amino acids experiments. All amino acids had induction times shorter than distilled water experiment.

The raw data of pressure - temperature versus time and pressure - torque versus time of all amino acid experiments are presented in Appendix A (Figures A.49 to A.54). Hydrate formation rates of experiments with amino acids are given in Figure 8.2 for 1, 600, 1200 and 1800 seconds. One conclusion that comes out from the mutual analysis of Figures 81. And 8.2 is that although hydrophobic compounds may delay hydrate formation compared to other amino acids, they exhibit higher hydrate formations rates compared to hydrophilic or neutral compounds.

Overall power consumption of hydrate formation with amino acids are presented in Figure 8.3. Except L-Lysine all other amino acids had less overall power consumptions compared to distilled water experiment.
These preliminary investigation of the effect of amino acids show that there is a potential to find some amino acids as hydrate promoters.

CHAPTER 9

CONCLUSIONS

This study mainly aimed to promote hydrate formation by investigating the effects of impeller – baffle configurations, and use of water soluble chemicals on the rate of hydrate formation. In order to achieve this goal of study, two stirred tanks were constructed and more than 50 experiments were run by using pure methane or methane – propane mixtures to form hydrates. Distilled water was used in most of the experiments as the water phase of hydrate formation but in 5 experiments, 1 weight percent of different amino acid aqueous solutions were used as the water phase. Under the light of the analysis of the experimental study the following conclusions were drawn:

- Single impeller experiments with methane showed that Rushton turbine (RT) impeller has better performance than up-pumping pitched blade turbine (PBTU) impeller, for all kinds of baffles.

- The produced gas consumption data, from the reactor systems used in this study, fit well to a third order quadratic equation as function of time.

- The initial hydrate formation rate is generally higher with the use of Rushton (RT) turbine as impeller, but the decline rate of hydrate formation also high compared to up-pumping pitched blade turbine (PRBTU).

- The higher decline rate of hydrate formation with higher initial hydrate formation is attributed to the restricted mass transfer between gas and water phases when higher amount of higher is formed at the gas - water interface initially. This actually shows the importance of the necessity the immediate and better removal of the solid hydrate particles from the gas – water interface.
- Another important item for the higher decline in hydrate formation is the exothermic nature of hydrate formation. The generated heat by hydrate formation must be removed as efficiently as possible to keep the driving force for hydrate formation at higher values.

- Use of dual impellers, either the same type or mixed, produced similar results of single impeller.

- In pure methane experiments, based on the low overall power consumption and high hydrate productivity, use of RT with full baffles proved to be a better combination for single impeller, for dual impellers and for dual mixed impellers where RT is the lower impeller.

- Hydrate formation process by gas mixtures become more complex because of different partition of gas components in free gas and solid hydrate phases.

- Propane is consumed more if hydrate is formed from a gas mixture of methane – propane. This fact brings another complexity of varying hydrate equilibrium curve during hydrate formation. As propane is consumed, hydrate equilibrium pressure gets higher for the given process temperature.

- Aqueous solutions of amino acids tested in this study showed shorter induction time and generally higher hydrate formation rates compared to distilled water experiment. This indicates a potential of finding hydrate promoters among these amino acids.
CHAPTER 10

RECOMMENDATIONS

This study was carried out by using stirred-tank reactors in batch mode. Although the results are quite satisfactory to delineate the effect of impeller – baffle configurations on the rate of hydrate formation there were some drawbacks mainly arising based on the batch operation mode. It is therefore recommended to operate the system semi-batch or continuous mode of operation.

The first option could be the injection of gas throughout the experiment rather than loading it at the beginning of experiment and run the experiment under constant feed of gas and constant pressure to convert the system into a semi-batch mode.

The second, but more complicated and expensive option is to have continuous mode in which the reactants (aqueous phase and the gas) are continuously flowing into and out of reactor. Since the flowing material out of reactor will be a mixture of water, gas and hydrate a separation operation is needed, firstly to separate the gas. Then, the remaining slurry of water and hydrate can also be separated to sample the hydrate phase for further investigation of hydrate parameters, such as composition of gas trapped in hydrate.

CURRICULUM VITAE

Name                      Sotirios LONGINOS
Email                     s.n.longinos@gmail.com
Nationality               Hellenic

EDUCATION

B.Sc.
2000– 2004: Technological Educational Institute of Central Greece (T.E.I.), Lamia, Electrical Engineering Department (4-year curriculum)

Diploma
2007– 2011: National Technical University of Athens (N.T.U.A.), Athens. School of Chemical Engineering (5 year curriculum, MSc equivalent)

M.Sc.
2012– 2013: University of Aberdeen (UOA), Aberdeen, School of Engineering, Master in Oil and Gas Engineering

Ph.D.
2014– 2020: Middle East Technical University (METU), Ankara Department of Petroleum and Natural Gas Engineering

EXPERIENCE

10/2003 – 03/2004  Electrical Engineer Trainee,
Piraeus Port Authority S.A., Port Services, GR

07/2010 –09/2010  Chemical Engineer Trainee,
Hellenic Petroleum S.A., Aspropyrgos, Attica, GR
(Refinery’s Conversion Units Department)

09/2009-07/2012  Research Assistant, School of Chemical Engineering, School of Chemical Engineering (Fuels and Lubricants Technology Laboratory)
Project Manager,
Local Host LTD, Liverpool, UK

Publications (Journal Articles)

Publications (Conference Articles)

Books-Book Chapters

Reviewer

2017-present Journal of Natural Gas Engineering and Science
2017-present Journal of Petroleum Engineering and Science
2017-present Journal of Environmental Geotechnics
2019-present Journal of Waste Management and Research

Additional Information

Affiliations Society of Petroleum Engineers • Energy Institute • Scientific Society of Technological Education Engineers (EETEM) • Institute of Corrosion • Society of Greek Chemical Engineers

Computer Skills Windows, Word, Excel, PowerPoint, Internet

Languages Greek : Fluent written and oral communication skills (native speaker)
**English**: Excellent written and oral communication skills (Certificate of Proficiency)

**Italian**: Good written and oral communication skills

**Arabian**: Good written and oral communication skills

**Military Obligations**  
Fulfilled: Signals Division • Hellenic Army (2004 – 2005)

**Interests**  
President of Undergraduate Student Association (N.T.U.A. & T.E.I.)
Representative in Rector Council & Senate (N.T.U.A & T.E.I.)
Student Representative in School Council (University of Aberdeen)
