This study focuses on kinematic calibration of industrial robots. Kinematic modeling, parameter identification and optimal pose selection methods are presented. A computer simulation of the kinematic calibration is performed using generated measurements with normally distributed noise. Furthermore, kinematic calibration experiments are performed on an ABB IRB 6600 industrial robot using full pose measurements taken by a laser tracking system. The kinematic model of the robot is developed using the modified Denavit-Hartenberg convention. A nonlinear least-squares method is employed during the parameter identification stage. According to the experiment results, the initial robot positioning errors are reduced by more than 80%.

Bu çalışma endüstriyel robotların kinematik kalibrasyonu üzerine odaklanmaktadır. Kine-
matik modelleme, parametre tanılama ve en iyi poz seçimi yöntemleri sunulmaktadır. Üretilen
normal dağılımlı gürültü içeren ölçümler kullanılarak bilgisayar ortamında kinematik kali-
brasyon benzetimleri elde edildi. Bunun yanı sıra, tam poz ölçümleri kullanılarak ABB IRB
6600 endüstriyel robotu üzerinde kinematik kalibrasyon deneyleri gerçekleştirildi. Robo-
tun kinematik modeli değiştirilmiş Denavit - Hartenberg notasyonu kullanılarak oluşturuldu.
Parametre tanılama işleminde doğrusal olmayan küçük kareler yöntemi kullanıldı. Deney
sonuçlarına göre robot konumlanma hataları %80 oranında azaltıldı.

ACKNOWLEDGMENTS

First and foremost, I would like to thank my advisor Asst. Prof. Dr. E. İlhan Konukseven for his guidance and direction throughout this research. I also would like to thank Prof. Dr. Tuna Balkan for his enlightening comments that guide me on the right path. Cenker Berk and Kübra Çelikkaya helped obtaining the measurements and provided the necessary tools for this study, many thanks. My fellow labmates in Virtual Reality Laboratory: Alican Tabakçı, Serter Yılmaz, Özgür Başer and Gökhan Bayer provided companionship during the whole period of the study for which I am grateful. Murat Bilen supported the study with his vision and knowledge on the subject. Last but not least, I dedicate my thesis to my family for their love and endless support.

CHAPTER 1

INTRODUCTION

Following the first installed industrial robot developed by Devol and Engelberger in 1961, the use of industrial robots rapidly increased and they quickly became an indispensable part of the manufacturing especially in the automotive industry. Today, they are used in a wide range of applications and are capable of performing the difficult tasks they are programmed for.

The most common method of robot programming is performed on the factory floor by manually teaching the robot the required poses of the task. While this method is tedious and even hazardous in some cases, it benefits from the robot’s ability to successfully repeat a previous instruction, a known quality of the industrial robots. On the other hand, emerging programming methods make it possible to create robot tasks in a virtual environment without interrupting the production cycle. While these new methods are proved to be less tiresome and more efficient, they require the robot to be able to move to an instructed pose accurately. This requirement put the robot’s accuracy into the spotlight.

The call for improving the accuracy of a robot without a redesign gave rise to the robot calibration techniques. Robot calibration is being studied extensively for the last twenty-five years, during which time, several studies have been conducted for better understanding the error sources on robots and different methods have been proposed accordingly. However, in an industrial point of view, a robot calibration method should not only be effective but also should be efficient in terms of the time, effort and cost to be invested.

In this study, a rapid and an effective approach to the industrial robot calibration is sought. According to this, the previous studies on the subject have been reviewed. A computer code featuring a graphical user interface is developed to be used for both the simulations and the calibration experiments. A novel and highly accurate measurement system is used to evaluate
the success of the calibration using additional measurements. Furthermore, an optimal pose selection algorithm is used to obtain the poses amongst the gathered measurements in terms of suppressing the measurement noise.

The pose error of a typical industrial robot and the part associated with the geometric parameters are inspected. Moreover, the effects of the measurement noise and the quality of the measurements on the improvement of the accuracy of an industrial robot as a result of the kinematic calibration are evaluated by simulations. The inverse geometric model is developed to apply the error correction methods.

According to the results of the research and by using the selected methods, the necessary computer tools along with graphical user interfaces are created which enable a progressive kinematic calibration that can be used on a range of industrial robots on the factory environment. These developed computer tools are further tested on calibration experiments which are proved to be efficient.

1.1 Objectives

The main objectives are:

- To investigate the robot calibration methods for their efficiency and to determine an approach to be taken to calibrate industrial robots.
- To code the mathematical routines and to design graphical user interfaces to be used during the simulations and the robot calibration procedure.
- To simulate the robot calibration using the designed tools and the generated measurements with normally distributed noise.
- To perform robot calibration experiments and to evaluate the errors associated with the nominal robot model.
- To evaluate the accuracy improvement of the robot as a result of the calibration using the selected measurements.
1.2 Outline of the Thesis

Chapter 2 presents background information on robot calibration and reviews the related works on the subject by presenting the approach and the techniques used on each step of the robot calibration. The modeling methods used in the study and their implementation on the robot under study are presented in Chapter 3. The details of the parameter identification and the pose selection method are discussed in Chapter 4. The details of the simulations and their results are presented at Chapter 5. The experiment on an industrial robot and its results are presented in Chapter 6. The reached conclusions and the future work are discussed in Chapter 7.
CHAPTER 2

REVIEW OF ROBOT CALIBRATION METHODS

This chapter reviews the existing methods of robot calibration. The related information on the subject like robot programming, performance evaluation and sources of error are given. The previous works on the literature is also presented.

2.1 Robot Error Sources and Performance Evaluation

The performance requirements for industrial robots differ by the task they perform. The two most frequently used performance criteria and their effect on different programming techniques are discussed in the next sections.

2.1.1 Accuracy and Repeatability

The accuracy and the repeatability of an industrial robot are largely used to evaluate its performance of reaching a desired pose. Repeatability is defined as the ability of the robot to reach the same taught position while accuracy is defined as the ability of the robot to precisely reach a programmed position [1]. Figure 2.1 shows the difference between the effect of accuracy and repeatability on the final position of the robot’s end effector.

Many factors credited to affect the overall robot accuracy including but not limited to deviations from nominal geometric parameters, joint offsets, link and joint compliance, gear trains, gear backlash, gear runout and thermal factors [2, 3, 4, 5, 6]. The errors in geometric parameters are mainly due to the tolerances in manufacturing and the assembly of the robots’ parts. The flexibility of robot joints and the link deflection under self-gravity and load are...
Figure 2.1: The effect of accuracy and repeatability [4].

attributed to compliance errors while thermal distortion and expansions of robot components are attributed to thermal errors [7].

The robot pose errors are more generally divided into geometric and non-geometric errors [2]. Geometric errors are caused by factors like joint offsets and deviations from the nominal geometric parameters. Non-geometric errors are caused by other factors like joint and link compliance, friction and clearance.

2.1.2 Programming

There are two common methods to program an industrial robot: online programming and offline programming. The online programming of industrial robots involves teaching the robot a sequence of poses manually, usually using a teach pendant, which all together compose a specific task. Another method is to design the task using separate software and then load it to the robot’s controller, which is known as offline programming. The visual robot simulation programs and the production stops due to the time it takes to program each robot online make
the latter method a better alternative. While the former method depends very much on the repeatability, a characteristic that is known to be adequately high on today’s industrial robots, the latter relies more on the accuracy of the industrial robots [3, 8]. In other words, for offline programming methods to be applicable, the robot model that is used offline must accurately describe the actual robot.

### 2.2 Robot Calibration

Robot calibration is a process that improves the accuracy of a robot by identifying a more accurate functional relationship between the nominal and the actual robot [5]. The aim of robot calibration is to improve the accuracy to reach the repeatability of the robot by modifications through software.

Bernhardt and Albright classified the robot calibration into two types [9]: static and dynamic calibration (Figure 2.3). Static calibration aims to identify the parameters that affect the static positioning characteristics of the robot like link lengths, joint offsets, gear runout, gear backlash, actuator and link elasticity and coupling factor. Dynamic calibration, on the other hand, deals with the identification of parameters that effect motion characteristics of the manipulator like friction and the mass and the stiffness of the links and the actuators.

A more general classification is made by Roth, Mooring and Ravani where they divided the robot calibration into three levels [5]: Level 1 is a joint level calibration which determines the
Joint offset errors. Level 2 is an entire robot kinematic model calibration which determines the basic kinematic geometry of the robot and the joint angle relationships. Finally, Level 3 is a non-kinematic calibration which determines the dynamic model of the robot.

In general, robot calibration is divided into four steps [5]:

- Modeling
- Measurements
- Identification
- Verification and Correction

### 2.2.1 Modeling

The first step of robot calibration is to establish a model that accurately maps the joint values to the end-effector pose. Everett and later Schroer identified the three requirements for this model to be used on the parameter identification stage as minimality, completeness and model continuity or proportionality [10, 11, 12].

Minimality refers to the use of minimal number of parameters by the kinematic model. Completeness is the ability of the model to map joint values into end-effector positions for all
arbitrary manipulators. Model continuity or proportionality requires small changes in the robot geometry to result small changes on the model parameters.

In an ideal case, this model accounts for all the factors that affect the robot pose errors. However, Mooring and Padavala argued that the effort associated with the more complex model is not justified if it improves just a small amount of the resulting robot accuracy [13]. Furthermore, a good number of studies show that the geometric factors have much greater influence on robot pose accuracy [3, 4, 7, 8, 13, 14, 15, 16].

The first study to include the non-geometric parameters to the calibration model is by Whitney et al. which they used a model with geometric parameters as well as non geometric parameters like joint compliance, backlash and gear transmission errors and calibrated a PUMA 560 robot using this model. Veitschegger and Wu calibrated a PUMA 560 robot by using position measurements to identify the geometric parameters and showed that the positioning errors are greatly reduced after the calibration [17]. Judd and Kasinski found out on their study with two AID-900 robots that the joint angle offsets were accountable for nearly 90% of the total rms error, deviations from nominal link parameters were accountable for a further 5% and gearing errors were only accountable for 1% of the total rms error [3]. Mooring and Padavela calibrated a PUMA 560 robot using four different models with increasing complexity [13]. They reduced the initial mean positioning error of five poses from 30.04 mm to 0.47 mm with a model consisting geometric parameters and joint offsets and to a further 0.42 mm by adding compliance to this model. Caenen and Angue improved the mean accuracy of a TH8 robot from 2.82 mm to 0.69 mm by only identifying the geometric parameters and to a further 0.58 mm by identifying the non-geometric parameters associated with compliance [15]. On their studies with Puma 760, Chen and Chao reduced the mean error distance of 5.9 mm to about 1 mm using geometric parameters and to an additional 0.28 mm by adding non-geometric parameters to characterize the twist angles in the second and the third joints and the backlash in third joint due to the gravitational effects [16]. Bernhardt showed the effect of identifying additional parameter classes on the positioning errors of a typical spot welding robot [14] (Figure 2.4). Gong et al. reduced the mean residual error of 30 positions from 1.059 mm to 0.126 mm by identifying only the geometric parameters and to a further 0.088 mm after calibrating for compliance errors of the second and the third joints [7]. After calibrating for these geometric and non-geometric errors, they also established and applied empirical thermal error models to estimate thermal errors by monitoring the temperature field.
at different operating conditions [7]. Jang et al. calibrated a DR06 robot for the geometric errors in addition to the non-geometric joint angle deformations resulting from a payload by dividing the robot workspace into several local regions and interpolating the identified errors of each local region to obtain continuous functions of joint angles in the workspace [18]. More recently, Gatla et al. calibrated a Staubli RX-130 robot by using only geometric parameters which improved the robot’s mean deviation of aiming a laser at a fixed point from 5.64 mm to 1.05 mm [8]. Lightcap, Hamner, Schmitz and Banks employed a two level optimization algorithm to identify the geometric and flexibility parameters of a PA10-6CE robot using measurements from a CMM where they reduced the positioning errors by 50 - 80% [19].

![Figure 2.4: Reduction of positioning error $\Delta TCP$ when identifying additional parameter classes from none to full model [14].](image)

Due to the results of these studies showing higher improvements in accuracy by just identifying the geometric parameters and also the complexity of adding the non-geometric parameters to the model, non-geometric factors are mainly discarded or neglected on the literature. The main idea behind it is, -barring the errors caused by non-geometric factors- robot accuracy can be greatly improved by identifying the geometric parameters of the robot. Moreover, since most robot controllers use geometric parameters on their model, it is easier to correct these parameters to improve the robot accuracy. This approach of identifying only the geometric
parameters is identical to the Level 2 calibration of Roth, Mooring and Ravani and it is still largely used.

The most widely used method of kinematic modeling is proposed by Denavit and Hartenberg where homogenous transformation matrices are used to represent the relationship between two consecutive link coordinate frames using four parameters [21] (Figure 2.5). These transformation matrices are then multiplied to create a transformation between the base and the end-effector coordinate systems. However, it has been shown by Hayati and Mirmirani that when two consecutive joint axes are parallel or nearly parallel, Denavit - Hartenberg model violates the model continuity or proportionality property since small changes in the robot geometry does not result small changes on the model parameters [22]. To overcome this, they introduced an alternative parameterization to be used in case of parallel or nearly parallel adjacent joint axes.

Alternative modeling techniques are also employed in robot calibration. Robertson and Dumont used genetic programming to obtain physical models by using mathematical operators that evolved to the equations based on the measurements taken from the robot [23]. Dolinsky et al. also used genetic programming to obtain evolved symbolic expressions of joint cor-
rection models for the first three joints of a PUMA 761 robot [24]. They reduced the mean positioning error of the robot with this method from 1.85 mm to 0.77 mm.

It should also be noted that all of the studies discussed so far employ parametric models and thus can be considered model-based approaches. There are also non-parametric or modeless methods where the errors are approximated by using the measured data. An example to this is the method proposed by Wang and Bai which uses a neural network algorithm to estimate the positioning errors from the measured errors of the grids on a calibration board [25].

### 2.2.2 Measurements

The second step of robot calibration is obtaining the required data from the robot under study. This data should be suitable to the model, in a sense, to relate the input of the established model to the output [5].

Measurement systems used in the robot calibration have great importance in terms of identifying the model parameters and evaluating the robot performance. They should meet the requirements of the calibration process in terms of accuracy and effectiveness. The measurement systems used in the previous robot calibration studies include laser trackers [7, 26], optical [8], photogrammetric [8, 18, 25, 27] and mechanical [24] systems, coordinate measuring machines [13, 19] and theodolites [2, 16].

Hidalgo and Brunn showed that these measurement systems differ from each other not only by their techniques but also by their characteristics like cost, sampling rate, set-up time, nominal accuracy and repeatability [28]. They also showed that high cost systems do not necessarily have higher accuracy, repeatability or resolution. Clearly, the most important properties are accuracy and repeatability, but an ideal measurement system should also cost less and require minimum amount of time to set-up. While most of the previous studies use optical and photogrammetric systems, laser tracking systems are more frequently used in the industry for their higher accuracy than their low-cost counterparts.

It should be noted that not all robot calibration methods require external measurement systems. Khalil et al. compared different geometric parameter calibration methods that use an external measurement device or the joint encoder readings alone to identify the geometric parameters [29]. The latter methods are considered as self-calibration methods on their study.
which use specific constraints like the terminal link being on the same pose (or position) or on the same plane for the chosen configurations.

### 2.2.3 Identification

The third step is to identify the parameters of the model using the gathered data. The most common methods used in this stage are formulated as regression problems to determine the parameters that minimize the error between the model and the measured data. Gauss-Newton algorithm is used for nonlinear models for it quickly converges provided that the initial estimates are close enough to the solution [30, 31]. This algorithm uses linear Taylor expansion of the nonlinear model and then employs ordinary least squares iteratively.

However, Gauss-Newton algorithm is known to perform poorly in case of singular or ill-conditioned matrices due to unidentifiable parameters, insufficient measurements and/or poor scaling issues [30, 31]. Levenberg - Marquardt algorithm [32, 33], a modified version of the Gauss-Newton algorithm, is a more robust choice in these cases.

Search algorithms can also be used on this stage but they are unavoidably slower. An example to this is the study by Liu et.al where they used genetic algorithm in their simulations to identify the geometric parameters of a PUMA 560 robot [34].

A lot of research on this step focuses on optimally selecting the measurement configurations to improve the performance of the identification. This is stated as the problem of determining a set of reachable robot measurement configurations that minimizes the effect of measurement noise on the identification of robot kinematic parameters [35]. These measurements are selected by using an observability index based on the identification Jacobian matrix. Driels and Pathre proposed to use the condition number of the identification Jacobian [36] while Born and Menq proposed the geometric mean of all the singular values of the identification Jacobian as the observability index [37]. Nahvi and Hollerbach proposed the minimum singular value and also the square of smallest non-zero singular value divided by the largest singular value of the identification Jacobian as observability indices [38, 39]. These observability indices are reviewed by Sun and Hollerbach where they relate them to the alphabet optimalities of the experimental design literature [39].

The methods used in finding the optimal measurements using the observability index also dif-
fer. Zhuang et.al proposed the use of the simulated annealing and later genetic algorithm on selecting the optimum measurements arguing that gradient-based methods frequently trapped into local minima [35, 40]. Sun and Hollerbach proposed a method called active robot calibration algorithm based on DETMAX algorithm of Mitchell [41] but using determinant-based updating observability index instead of an eigenvalue-based one [42]. Watanabe et al. proposed an automatic calibration method that determines the poses to be measured based on their condition number [27]. It should also be noted that Khalil and Besnard pointed out that randomly selected measurements generally have sufficient condition number [29].

### 2.2.4 Verification and Correction

The final step of robot calibration is correcting the errors of the robot. The simplest way to do this is by updating the identified parameter values inside the robot controller. However, most robot controllers employ only the geometric parameters on their model. Furthermore, not all robot controllers allow the nominal model parameters to be changed. Another method is to change the robot program by updating the robot targets of the task. This requires the inverse model of the robot to generate so-called fake targets. A final way is using an external unit to correct the errors real time.

It is also a good practice to validate the accuracy of the identification prior to the correction procedure. Since the identification algorithms use the supplied measurement data for estimating the model parameters, additional measurements should be obtained from the robot to verify these estimated parameters. This will also help to have a basic idea on the pose errors before and after the calibration.
CHAPTER 3

KINEMATIC MODELING

This chapter presents the information on kinematic modeling of the IRB 6600 robot used during the study. The mathematical background on the kinematic modeling and the modeling of the robot under study are discussed in detail.

3.1 Mathematical Background

This section presents the representation of position and orientation, homogenous transformation and the geometric representation of serial-link robots, specifically method of Denavit and Hartenberg. The sources used during this chapter are [6, 31, 43].

3.1.1 Representation of Position and Orientation

3.1.1.1 Position

The 3x1 position vector:

\[
\begin{pmatrix}
P_x \\
P_y \\
P_z \\
\end{pmatrix}
\]

represents the position of the origin of the coordinate frame A relative to coordinate frame B [31, 43]. The components \(P_x\), \(P_y\) and \(P_z\) of this vector are the Cartesian coordinates of the origin of the coordinate frame A in the B frame.
### 3.1.1.2 Orientation

Let the unit vectors giving the principal directions of coordinate system B denoted as \( \hat{x}_B, \hat{y}_B, \hat{z}_B \). They can be written in terms of the coordinate system A as \( \hat{A}_B \). These three unit vectors can be stacked on the columns of a 3x3 matrix:

\[
A_R B = \begin{bmatrix}
\hat{A}_B \\
\hat{A}_B \\
\hat{A}_B
\end{bmatrix} = \begin{bmatrix}
\hat{B}_A \cdot \hat{x}_A & \hat{B}_A \cdot \hat{y}_A & \hat{B}_A \cdot \hat{z}_A \\
\hat{B}_A \cdot \hat{x}_A & \hat{B}_A \cdot \hat{y}_A & \hat{B}_A \cdot \hat{z}_A \\
\hat{B}_A \cdot \hat{x}_A & \hat{B}_A \cdot \hat{y}_A & \hat{B}_A \cdot \hat{z}_A
\end{bmatrix}
\]

which is called the rotation matrix. The rotation of the frame A through an angle \( \theta \) about the \( \hat{x}_B \) axis is:

\[
R_x(\theta) = \begin{bmatrix}
1 & 0 & 0 \\
0 & \cos \theta & -\sin \theta \\
0 & \sin \theta & \cos \theta
\end{bmatrix}
\]

about the \( \hat{y}_B \) axis is:

\[
R_y(\theta) = \begin{bmatrix}
\cos \theta & 0 & \sin \theta \\
0 & 1 & 0 \\
-\sin \theta & 0 & \cos \theta
\end{bmatrix}
\]

and about the \( \hat{z}_B \) axis is:

\[
R_z(\theta) = \begin{bmatrix}
\cos \theta & -\sin \theta & 0 \\
\sin \theta & \cos \theta & 0 \\
0 & 0 & 1
\end{bmatrix}
\]

### 3.1.2 Homogenous Transformation

Homogenous transformation combines the position and the orientation.

\[
B T_A = \begin{bmatrix}
B_R A & B P_A \\
0 & 1
\end{bmatrix}
\]

The homogeneous transformation of a translation along an axis is denoted Trans. According to this, the translation of \( l \) along the \( \hat{x} \) axis can be written as:

\[
Trans(\hat{x}, \theta) = \begin{bmatrix}
0 & 0 & 0 & l \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1
\end{bmatrix}
\]
The homogeneous transformation of a rotation about an axis is denoted by Rot. According to this, the rotation through an angle $\theta$ about the $\hat{x}$ axis can be written as:

$$\text{Rot}(\hat{x}, \theta) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta & 0 \\ 0 & \sin \theta & \cos \theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$  \hspace{1cm} (3.8)

### 3.1.3 Geometric Representation

Denavit and Hartenberg introduced a widely adopted convention for assigning frames to the links of the robot [21]. A modified version of this convention by Khalil and Dombre is used throughout this research [6]. This convention has an advantage of using the same subscript for the parameters defining a transformation between two consecutive frames while it has a drawback of denoting link lengths with a parameter having the same index of the consecutive link.

The two main assumptions are: the links are perfectly rigid and the joints are ideal in a sense that there is neither backlash nor elasticity [6]. A serial robot is composed of a sequence of $n-1$ links and $n$ joints where link 0 is the base of the robot and link $n$ is the terminal link [6]. Joint $i$ connects the link $i$ to the link $i-1$ and its variable is denoted by $\theta_i$ [6]. A frame $R_i$ is attached to each link $i$ with [6]:

- The $z_i$ axis is located along the axis of joint $i$.
- The $x_i$ axis is located along the common normal between the $z_i$ and $z_{i+1}$ axis. If $z_i$ and $z_{i+1}$ axes are parallel or collinear, the choice of $x_{i+1}$ is not unique. The intersection of $x_i$ axis and $z_i$ axes defines the origin $O_i$. If the joint axes intersect, the origin is at the point of intersection of the joint axes.
- The $y_i$ axis is located using the right-hand rule to form $(x_i,y_i,z_i)$ coordinate system.

The transformation matrix from frame $R_{i-1}$ to frame $R_i$ is expressed using the following four geometric parameters (Figure 3.1) [6]:

- Link twist: $\alpha_i$ is the angle between $z_{i-1}$ and $z_i$ about $x_{i-1}$
Figure 3.1: The parameters $\alpha_i$, $a_i$, $\theta_i$ and $d_i$ [31].

- Link length: $a_i$ is the distance between $z_{i-1}$ and $z_i$ along $x_{i-1}$
- Joint angle: $\theta_i$ is the angle between $x_{i-1}$ and $x_i$ about $z_i$
- Link offset: $d_i$ is the distance between $x_{i-1}$ and $x_i$ along $z_i$

And the transformation matrix defining the frame $R_i$ relative to the frame $R_{i-1}$ is:

$$
^{i-1}T_i = \begin{bmatrix}
\cos \theta_i & -\sin \theta_i & 0 & a_i \\
\cos \alpha_i \sin \theta_i & \cos \alpha_i \cos \theta_i & -\sin \alpha_i & -d_i \sin \alpha_i \\
\sin \alpha_i \sin \theta_i & \sin \alpha_i \cos \theta_i & \cos \alpha_i & d_i \cos \alpha_i \\
0 & 0 & 0 & 1
\end{bmatrix}
$$

(3.9)

As it is mentioned in the previous chapter, Denavit - Hartenberg representation faces a problem when two joint axes are parallel. When two consecutive joint axes $i-1$ and $i$ are parallel, the $x_{i-1}$ axis is chosen arbitrarily along one of the common normals between them. If $z_i$ or $z_{i-1}$ gets slightly misaligned, the common normal becomes uniquely defined and a big variation in the parameter $d_{i-1}$ might occur [5, 6]. To overcome this problem, Hayati introduced a new parameter $\beta_i$ representing a rotation around the $y_{i-1}$ axis [22]. Thus, the general transformation matrix between two frames with consecutive parallel joints becomes [6] (Figure 3.2):
Figure 3.2: The additional parameter $\beta_i$ for consecutive parallel joints. [31].

\[ \begin{pmatrix} c\beta_i c\theta_i + s\alpha_i s\beta_i s\theta_i \\ s\alpha_i s\beta_i c\theta_i - c\beta_i s\theta_i \\ c\alpha_i s\beta_i a_i c\beta_i + d_i c\alpha_i s\beta_i \\ a_i \end{pmatrix} \] (3.10)

where $c\gamma_i$ stands for $\cos\gamma_i$ and $s\gamma_i$ stands for $\sin\gamma_i$. In such cases, the parameter $\beta_i$ is identified instead of $d_i$.

### 3.1.4 Forward Kinematics

The forward kinematics problem for a serial-chain manipulator is defined as finding the pose (position and orientation) of the end-effector relative to the base given the values of the joint variables and the geometric link parameters [31]. It can be solved by calculating the transformation between the frames fixed in the end-effector and in the base [31]. This transformation can be obtained by simply concatenating the transformations between the fixed frames of the adjacent links [31]:

\[ ^0T_n = ^0T_1 ^1T_2 \cdots ^{n-2}T_{n-1} ^{n-1}T_n \] (3.11)
3.1.5 Inverse Kinematics

The inverse kinematics problem for a serial-chain manipulator is defined as finding the values of the joint variables given the pose of the end-effector relative to the base and the geometric link parameters [31].

This problem can be solved algebraically or geometrically to obtain a closed-form solutions or using numerical methods. While closed-form solutions depend on the particular robot, they are faster than numerical solutions [31]. These solutions use particular geometric features like spherical wrist where three consecutive revolute joint axes intersect at a common point [31]. A closed-form solution of an industrial robot used in this study will be presented in the later sections.

3.2 Kinematic Modeling of ABB IRB 6600

This section presents the modeling of ABB IRB 6600 industrial robot.

3.2.1 Robot Description

ABB IRB 6600 industrial robot is selected as the robot of interest in this study. The version of the particular robot is 2.55 / 175. This version numbers represent that its maximum reach at wrist center is 2.55 meters and have a maximum handling capacity of 175 kg while it weighs 1.7 tons [44].

The positioning accuracy of the robot is reported on the production specification as 0.02 - 0.09 mm and the positioning repeatability is reported to as 0.08 - 0.18 mm [44]. The positioning accuracy of the calibrated robot is reported to be 97% within 1 mm with an average of 0.5 mm and a maximum value of 1.2 mm [44]. The joint axis resolution is reported as 0.001° - 0.005°.

ABB IRB 6600 industrial robot has six joint axes as shown in Figure 3.3. The type and the range of motion of these joint axes are shown in Table 3.1.
3.2.2 Kinematic Modeling

The link lengths of the robot are shown in Figure 3.4. The modified Denavit - Hartenberg convention by Khalil and Dombre is used to attach the frames on each link and to represent the geometric link parameters of the robot [6]. The attached frames are shown in Figure 3.5.

3.2.2.1 Reference Frame

The base frame is assigned to be aligned with the first frame when $\theta_1=0$, the same way it is defined on the robot controller as shown in Figure 3.6. Since an external measurement
system might obtain its measurements relative to a world reference frame, there is a need to define this reference frame. Six parameters are required to locate the robot base frame relative to a reference frame [6]:

\[
R_T^R = \text{Rot}(z, \gamma_R)\text{Trans}(z, b_R)\text{Rot}(x, \alpha_R)\text{Trans}(x, a_R)\text{Rot}(z, \theta_R)\text{Trans}(z, d_R) \tag{3.12}
\]

Then, the transformation matrix from the reference frame to the first link frame becomes:

\[
R_T^1 = \text{Rot}(z, \gamma_R)\text{Trans}(z, b_R)\text{Rot}(x, \alpha_R)\text{Trans}(x, a_R)\text{Rot}(z, \theta_R)\text{Trans}(z, d_R) \tag{3.13}
\]

\[
\text{Rot}(x, \alpha_1)\text{Trans}(x, a_1)\text{Rot}(z, \theta_1)\text{Trans}(z, d_1)
\]

having \(\alpha_1\) and \(a_1\) as zero, Eq. 3.14 can be written as:

\[
R_T^1 = \text{Rot}(x, \alpha_0)\text{Trans}(x, a_0)\text{Rot}(z, \theta_0)\text{Trans}(z, d_0) \tag{3.14}
\]

\[
\text{Rot}(x, \alpha'_1)\text{Trans}(x, a'_1)\text{Rot}(z, \theta'_1)\text{Trans}(z, d'_1)
\]

where \(\alpha_0=0, a_0=0, \theta_0=\gamma_R, d_0=b_R, \alpha'_1=\alpha_R, a'_1=a_R, \theta'_1=\theta_1+\theta_R\) and \(d'_1=d_1+d_R\) [6]. For simplicity, the parameters \(\alpha'_1, a'_1, \theta'_1\) and \(d'_1\) will be referred as \(\alpha_1, a_1, \theta_1\) and \(d_1\) respectively.
3.2.2.2 End-Effector Frame

The end-effector frame is assigned according to the mounting of T-Mac probe as shown in Figure 6.1. Six parameters are required to locate the end-effector frame relative to last link frame[6]:

$$ {^6T_L} = \text{Rot}(z, \gamma_L)\text{Trans}(z, b_L)\text{Rot}(x, \alpha_L)\text{Trans}(x, a_L)\text{Rot}(z, \theta_L)\text{Trans}(z, d_L) \quad (3.15) $$

Then, the transformation matrix from the fifth link frame to the end-effector frame becomes:

$$ {^5T_L} = \text{Rot}(x, \alpha_6)\text{Trans}(x, a_6)\text{Rot}(z, \theta_6)\text{Trans}(z, d_6) \quad (3.16) $$

$$ \text{Rot}(z, \gamma_L)\text{Trans}(z, b_L)\text{Rot}(x, \alpha_L)\text{Trans}(x, a_L)\text{Rot}(z, \theta_L)\text{Trans}(z, d_L) $$

which can be written as:

$$ {^5T_L} = \text{Rot}(x, \alpha_6)\text{Trans}(x, a_6)\text{Rot}(z, \theta^*_6)\text{Trans}(z, d^*_6) \quad (3.17) $$

$$ \text{Rot}(x, \alpha_L)\text{Trans}(x, a_L)\text{Rot}(z, \theta_L)\text{Trans}(z, d_L) $$
where $\theta_L' = \theta_6 + \theta_L$ and $d_L' = d_6 + d_L$ [6]. For simplicity, the parameters $\theta_L'$ and $d_L'$ will be referred as $\theta_L$ and $d_L$ respectively.

![Figure 3.6: The base frame of the ABB IRB 6600 [44].](image)

Since the second and third joints of the robot are parallel, Hayati parameter [22] is also included to the model and this parameter is calibrated instead of $d_3$. Following the frame assignments, the modified Denavit-Hartenberg parameters and the Hayati parameter of the robot are determined as shown in Table 3.2.

**Table 3.2: Nominal Denavit-Hartenberg and Hayati parameters of the ABB IRB 6600 robot.**

3.2.3 Forward Kinematics of ABB IRB 6600

Using Eq. 3.9 and 3.10 together with the Table 3.2, the transformation from the reference frame to the end-effector frame of the robot can be calculated as:

\[ R_{T_L} = R_{T_0} T_1 T_2^2 T_3^3 T_4^4 T_5^5 T_6^6 R_L = \begin{bmatrix} R_{R_L} & R_{P_L} \\ 0 & 1 \end{bmatrix} \tag{3.18} \]

where \( R_{R_L} \) is the 3x3 rotation matrix and \( R_{P_L} \) is the 3x1 position vector.

3.2.4 Inverse Kinematics of ABB IRB 6600

The closed-form solution of the inverse kinematic model is developed algebraically using the derivations from Khalil and Dombre [6]. Only the non-zero link offsets and link lengths of the Table 3.2 are taken into consideration along with the joint angles. It can be seen from Figure 3.5 that the fourth, fifth and sixth joint axes intersect forming a spherical wrist. The origins of these frames are located at the same position making \( ^0 P_6 = ^0 P_4 \). This can be represented by:

\[ \begin{bmatrix} p_x \\ p_y \\ p_z \end{bmatrix} = ^0 T_1 T_2^2 T_3^3 T_4 \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \tag{3.19} \]

Multiplying Eq. 3.19 by \( ^2 T_0 \) on both sides yields:

\[ \begin{bmatrix} d_1 \sin \theta_2 - a_2 \cos \theta_2 - p_z \sin \theta_2 + p_x \cos \theta_1 \cos \theta_2 + p_y \cos \theta_1 \sin \theta_2 \\ d_1 \cos \theta_2 - p_z \cos \theta_2 + a_2 \sin \theta_2 - p_x \cos \theta_1 \sin \theta_2 - p_y \sin \theta_1 \sin \theta_2 \\ p_y \cos \theta_1 - p_x \sin \theta_1 \end{bmatrix} = \begin{bmatrix} a_3 + a_4 \cos \theta_3 - d_4 \sin \theta_3 \\ d_4 \cos \theta_3 + a_4 \sin \theta_3 \\ 0 \end{bmatrix} \tag{3.20} \]

The three equations from Eq. 3.20 can be written as:

\[ a_4 \cos \theta_3 - d_4 \sin \theta_3 = (d_1 - p_x) \sin \theta_2 - (a_2 - p_x \cos \theta_1 - p_y \sin \theta_1) \cos \theta_2 - a_3 \tag{3.21} \]

\[ a_4 \sin \theta_3 + d_4 \cos \theta_3 = (d_1 - p_x) \cos \theta_2 + (a_2 - p_x \cos \theta_1 - p_y \sin \theta_1) \sin \theta_2 \tag{3.22} \]

\[ p_y \cos \theta_1 - p_x \sin \theta_1 = 0 \tag{3.23} \]
Eq. 3.23 can be used to solve for $\theta_1$ as [6]:

$$\begin{cases} \theta_1 = \tan^{-1}(p_y, p_x) \\ \theta'_1 = \theta_1 + \pi \end{cases} \quad (3.24)$$

Eq. 3.22 and Eq. 3.21 can be written as:

$$W_1 \cos \theta_3 + W_2 \sin \theta_3 = X_1 \sin \theta_2 + Y_1 \cos \theta_2 + Z_1 \quad (3.25)$$

$$W_1 \sin \theta_3 - W_2 \cos \theta_3 = X_2 \cos \theta_2 - Y_2 \sin \theta_2 + Z_2 \quad (3.26)$$

where

$$\begin{cases} W_1 = a_4 \\ W_2 = d_4 \\ X = d_1 - p_x \\ Y = a_2 - p_x \cos \theta_1 - p_y \sin \theta_1 \\ Z_1 = 0 \\ Z_2 = -a_3 \end{cases} \quad (3.27)$$

Squaring and adding the both sides of the Eq. 3.22 and 3.21 cancels the terms with $\theta_3$ and yields an equation containing only $\theta_2$ in the form:

$$B_1 \sin \theta_2 + B_2 \cos \theta_2 = B_3 \quad (3.28)$$

where

$$\begin{cases} B_1 = -2a_3(d_1 - p_x) \\ B_2 = 2a_3(a_2 - p_x \cos \theta_1 - p_y \sin \theta_1) \\ B_3 = a_4^2 - (d_1 - p_x)^2 - (a_2 - p_x \cos \theta_1 - p_y \sin \theta_1)^2 - a_3^2 \end{cases} \quad (3.29)$$

From Eq. 3.28 [6]:

$$\sin \theta_2 = \frac{B_1 B_3 + \epsilon B_2 \sqrt{B_1^2 + B_2^2 - B_3^2}}{B_1^2 + B_2^2} \quad (3.30)$$

$$\cos \theta_2 = \frac{B_2 B_3 - \epsilon B_1 \sqrt{B_1^2 + B_2^2 - B_3^2}}{B_1^2 + B_2^2} \quad (3.31)$$

where $\epsilon = \pm 1$. Thus $\theta_2$ can be solved by using Eq. 3.30 and 3.31 as:

$$\theta_2 = \tan^{-1}(\sin \theta_2, \cos \theta_2) \quad (3.32)$$

Having found $\theta_2$, Eq. 3.22 and 3.21 reduce to the form:

$$X_1 \sin \theta_3 + Y_1 \cos \theta_3 = Q_1 \quad (3.33)$$

$$X_2 \sin \theta_3 + Y_2 \cos \theta_3 = Q_2 \quad (3.34)$$
where

\[
\begin{align*}
X_1 &= Y_2 = a_4 \\
X_2 &= -Y_1 = -d_4 \\
Q_1 &= (d_1 - p_z)\cos \theta_2 + (a_2 - p_x \cos \theta_1 - p_y \sin \theta_1)\sin \theta_2 \\
Q_2 &= (d_1 - p_z)\sin \theta_2 - (a_2 - p_x \cos \theta_1 - p_y \sin \theta_1)\cos \theta_2 - a_3
\end{align*}
\] (3.35)

Multiplying the Eq. 3.33 by \( Y_2 \) and 3.34 by \( Y_1 \) and adding both sides yields [6]:

\[
\sin \theta_3 = \frac{Q_1 Y_2 - Q_2 Y_1}{X_1 Y_2 - X_2 Y_1}
\] (3.36)

Multiplying the Eq. 3.33 by \( X_2 \) and 3.34 by \( X_1 \) and adding both sides yields [6]:

\[
\cos \theta_3 = \frac{Q_2 X_1 - Q_1 X_2}{X_1 Y_2 - X_2 Y_1}
\] (3.37)

Thus \( \theta_3 \) can be solved by using Eq. 3.36 and 3.37 as:

\[
\theta_3 = \text{atan2}(\sin \theta_3, \cos \theta_3)
\] (3.38)

After finding \( \theta_1 \), \( \theta_2 \) and \( \theta_3 \), the rotation matrix of the third frame relative to the base frame, \( ^0R_3 \), can be calculated. The rotation matrix of the final frame relative to the base frame is also known and can be written as:

\[
^0R_6 = \begin{bmatrix}
  s_x & n_x & a_x \\
  s_y & n_y & a_y \\
  s_z & n_z & a_z
\end{bmatrix}
\] (3.39)

Thus the rotation matrix \( ^3R_6 \) can be calculated from:

\[
^3R_6 = ^3R_0 \cdot ^0R_6 = \begin{bmatrix}
  f_x & g_x & h_x \\
  f_y & g_y & h_y \\
  f_z & g_z & h_z
\end{bmatrix} \begin{bmatrix}
  s_x & n_x & a_x \\
  s_y & n_y & a_y \\
  s_z & n_z & a_z
\end{bmatrix}
\] (3.40)

The same way, calculating \( ^4R_6 \):

\[
^4R_6 = ^4R_3 \cdot ^3R_6 = \begin{bmatrix}
  f_x \cos \theta_4 - f_x \sin \theta_4 & g_x \cos \theta_4 - g_x \sin \theta_4 & h_x \cos \theta_4 - h_x \sin \theta_4 \\
  -f_x \cos \theta_4 - f_x \sin \theta_4 & -g_x \cos \theta_4 - g_x \sin \theta_4 & -h_x \cos \theta_4 - h_x \sin \theta_4 \\
  f_y & g_y & h_y
\end{bmatrix}
\]

\[
= \begin{bmatrix}
  \cos \theta_5 \cos \theta_6 & -\cos \theta_5 - \sin \theta_5 & -\sin \theta_5 \\
  \sin \theta_6 & \cos \theta_6 & 0 \\
  \cos \theta_6 \sin \theta_5 & -\sin \theta_6 \sin \theta_5 & \cos \theta_5
\end{bmatrix}
\] (3.41)
From the second rows and third columns of both sides of Eq. 3.41:

\[-h_z \cos \theta_4 - h_x \sin \theta_4 = 0 \quad (3.42)\]

Eq. 3.42 can be used to solve for \( \theta_4 \) as [6]:

\[
\begin{align*}
\theta_4 &= \text{atan2}(h_z, -h_x) \\
\theta'_4 &= \theta_1 + \pi
\end{align*}
\]

(3.43)

Again from Eq. 3.41:

\[
\begin{align*}
\sin \theta_5 &= -h_x \cos \theta_4 + h_z \sin \theta_4 \\
\cos \theta_5 &= h_y
\end{align*}
\]

(3.44)

(3.45)

Solving Eq. 3.44 and 3.45 together for \( \theta_5 \) [6]:

\[
\theta_5 = \text{atan2}(\sin \theta_5, \cos \theta_5)
\]

(3.46)

And lastly from Eq. 3.41:

\[
\begin{align*}
\sin \theta_6 &= -f_z \cos \theta_4 - f_x \sin \theta_4 \\
\cos \theta_6 &= -g_z \cos \theta_4 - g_x \sin \theta_4
\end{align*}
\]

(3.47)

(3.48)

Solving Eq. 3.47 and 3.48 together for \( \theta_6 \) [6]:

\[
\theta_6 = \text{atan2}(\sin \theta_6, \cos \theta_6)
\]

(3.49)
CHAPTER 4

PARAMETER IDENTIFICATION

This chapter gives information about the pose selection and the parameter identification methods used during the study by their formulation, analysis and utilization to the model developed on the previous chapter.

4.1 Parameter Identification Methods

Parameter identification methods used on the previous robot calibration studies are discussed on the second chapter. Two of these algorithms based on least squares are presented in this section.

4.1.1 Gauss-Newton Algorithm

The nonlinear kinematic model can be written as [30, 31]:

$$ y = f(w, x) $$

(4.1)

where $w$ is the $p \times 1$ parameter vector to be identified, $y$ is the $n \times 1$ output vector, $f(w, x)$ is $n \times 1$ vector of functions and $x$ is the $k \times 1$ input vector. When there are $m$ measurements having $n$ pose components, Eq. 4.1 can be written as [31, 30]:

$$ y_j = f_j(w, x_j) \quad (j = 1, \ldots, m) $$

(4.2)

where $f_j(w, x_j) = [f_{j1}(w, x_j) \ldots f_{jn}(w, x_j)]^T$ is the $n \times 1$ vector of functions, $y_j = [y_{j1} \ldots y_{jn}]^T$ is the $n \times 1$ output vector and $x_j = [x_{j1} \ldots x_{jk}]^T$ is the $k \times 1$ input vector for the $j^{th}$ measurement.
The least-square solution seeks the estimate $\hat{w}$ of the actual value of the parameter vector $w$ that minimizes the sum of squares of the error between the model and the measurements:

$$S(w) = \sum_{j=1}^{m} \| y_j - f(w, x_j) \|^2 = r^T r$$

(4.3)

where $r$ is the nm x 1 residual vector:

$$r = \begin{bmatrix} y_1^1 - f_1^1(w, x_1^1) \\ y_2^1 - f_2^1(w, x_1^1) \\ \vdots \\ y_n^n - f_n^n(w, x_1^n) \\ \vdots \\ y_{n-1}^m - f_{n-1}^m(w, x_m^n) \\ y_n^m - f_n^m(w, x_m^m) \end{bmatrix}$$

(4.4)

Taking linear Taylor series approximation of $f_j(w, x_j)$ about an initial estimate of the parameter vector $w_a$ yields:

$$f_j(w, x_j) \approx f_j(w_a, x_j) + \frac{\partial f_j(w, x_j)}{\partial w} \bigg|_{w=w_a} (w - w_a)$$

(4.5)

Solving for the minimum of Eq. 4.3 with respect to $w$ using Eq. 4.5 yields [30]:

$$(w - w_a) = \delta_a = (J_a^T J_a)^{-1} J_a^T r$$

(4.6)

where

$$J_a = \begin{bmatrix} \frac{\partial f_1^1(w, x_1^1)}{\partial w} \bigg|_{w=w_a} \\ \vdots \\ \frac{\partial f_n^n(w, x_1^n)}{\partial w} \bigg|_{w=w_a} \\ \vdots \\ \frac{\partial f_{n-1}^m(w, x_m^n)}{\partial w} \bigg|_{w=w_a} \\ \frac{\partial f_n^m(w, x_m^m)}{\partial w} \bigg|_{w=w_a} \end{bmatrix}$$

(4.7)

is the nm x p identification Jacobian matrix. Eq. 4.29 is called Gauss-Newton step [30]. Thus, given an initial estimate $w_a$, the next estimate can be calculated from:

$$w_{a+1} = w_a + \delta_a = w_a + (J_a^T J_a)^{-1} J_a^T r$$

(4.8)

which is repeated iteratively until the error is less than a tolerance value or a convergence is obtained.

### 4.1.2 Levenberg - Marquardt Algorithm

Gauss-Newton algorithm is known for its fast convergence. However, a problem arise when the matrix $J^T J$ is not invertible for being singular or ill-conditioned. Levenberg and Marquardt
Algorithm solves this problem by modifying the Gauss-Newton step as [30, 32, 33]:

\[
\delta^a = (J^a^T J^a + \mu^a D^a)^{-1} J^a^T r
\]  

(4.9)

where \( D^a \) is a diagonal matrix containing positive elements and \( \mu^a \) is a scalar. \( D^a \) can be chosen as identity matrix for simplicity or the diagonal elements of the matrix \( J^a^T J^a \) are used. \( \mu^a \) is generally set as a low value and it is multiplied by a factor whenever Eq. 4.3 is not reduced as a result of the iteration.

4.2 Parameter Identification of ABB IRB 6600

In this section, the details of the employment of the parameter identification procedure for ABB IRB 6600 robot are presented.

4.2.1 Formulation

For the utilized robot calibration scheme and according to Eq 4.2 and 4.8, output vector consists of the pose measurements, input vector consists of the joint variables and the parameters not included on the identification and the vector of functions are the nonlinear equations obtained from Eq 3.18.

The parameter vector is a 30 x 1 vector consisting of all 30 parameters of Table 3.2:

\[
w = [a_1 \ldots a_L \ a_1 \ldots a_L \ d_0 \ldots d_2 \ d_4 \ldots d_L \ \theta_0 \ldots \theta_L \ \beta_3]^T
\]  

(4.10)

with the assumption of all parameters being identifiable. The identifiability of the parameters will be investigated on the next section.

Let \( m \) pose measurements be taken from the robot’s end-effector frame having three position and three orientation components. The joint configurations of the robot corresponding to the \( j^{th} \) measurement can be expressed as:

\[
\theta^j = [\theta^j_{1,\text{meas}} \ \theta^j_{2,\text{meas}} \ \theta^j_{3,\text{meas}} \ \theta^j_{4,\text{meas}} \ \theta^j_{5,\text{meas}} \ \theta^j_{6,\text{meas}}]^T \quad (j = 1, \ldots, m)
\]  

(4.11)

and the \( j^{th} \) measurement can be expressed as:

\[
y^j = [p^j_{x,\text{meas}} \ p^j_{y,\text{meas}} \ p^j_{z,\text{meas}} \ \gamma^j_{x,\text{meas}} \ \gamma^j_{y,\text{meas}} \ \gamma^j_{z,\text{meas}}]^T \quad (j = 1, \ldots, m)
\]  

(4.12)
where the superscript ‘meas’ denotes that these are obtained from measurements. Same way, the pose of the end-effector for the \( j \)th measurement configuration can be calculated using Eq. 3.18 and 4.11 together with the parameters from Table 3.2 as:

\[
{^R}_T^L_{L,\text{calc}} \begin{bmatrix}
{^R}_R^L_{L,\text{calc}} & {^p}_x^j_{\text{calc}} \\
{^p}_y^j_{\text{calc}} & {^p}_z^j_{\text{calc}} \\
0 & 1
\end{bmatrix} (j = 1, \ldots, m) \tag{4.13}
\]

where the superscript ‘calc’ denotes that these are obtained from calculations. In order to form the residue vector for the \( j \)th measurement configuration, the difference between the calculated and the measured position and orientation of the end-effector is needed to be obtained:

\[
{r}^j = \begin{bmatrix}
\Delta{^p}_j \\
\Delta{^O}_j
\end{bmatrix} (j = 1, \ldots, m) \tag{4.14}
\]

Since the measurement system represents the orientation using Z-Y-X Euler angles, the Euler angles from the matrix \( {^R}_R^L_{L,\text{calc}} \) can be extracted. However, the calculation of the identification Jacobian will be far too tedious using this approach. For this reason, the approach of Khalil and Dombre is used to represent the orientation error by using rotation matrices. The rotation matrix from the \( j \)th measured orientation can be calculated by:

\[
{^R}_R^L_{L,\text{meas}} = \text{Rot}(z, \gamma^j_{z,\text{meas}}) \text{Rot}(y, \gamma^j_{y,\text{meas}}) \text{Rot}(x, \gamma^j_{x,\text{meas}}) \tag{4.15}
\]

and the orientation error can be expressed as [6]:

\[
\Delta{^O}_j = {u}^j{\alpha}^j \tag{4.16}
\]

where

\[
{^R}_R^L_{L,\text{meas}} = \text{Rot}({u}^j, {\alpha}^j)^{{^R}_R^L_{L,\text{calc}}} \tag{4.17}
\]
Thus, the 6m x 1 residue vector becomes:

$$
\mathbf{r} = \begin{bmatrix}
  r_1 \\
  r_2 \\
  \vdots \\
  r_m
\end{bmatrix} = \begin{bmatrix}
  \Delta \mathbf{P}^1 \\
  \Delta \mathbf{O}^1 \\
  \vdots \\
  \Delta \mathbf{P}^m \\
  \Delta \mathbf{O}^m
\end{bmatrix} = \begin{bmatrix}
  p_{x,\text{meas}}^1 - p_{x,\text{calc}}^1 \\
  p_{y,\text{meas}}^1 - p_{y,\text{calc}}^1 \\
  p_{z,\text{meas}}^1 - p_{z,\text{calc}}^1 \\
  u_1^1 \alpha^1 \\
  u_2^1 \alpha^1 \\
  u_3^1 \alpha^1 \\
  \vdots \\
  p_{x,\text{meas}}^m - p_{x,\text{calc}}^m \\
  p_{y,\text{meas}}^m - p_{y,\text{calc}}^m \\
  p_{z,\text{meas}}^m - p_{z,\text{calc}}^m \\
  u_1^m \alpha^m \\
  u_2^m \alpha^m \\
  u_3^m \alpha^m
\end{bmatrix} \quad (4.18)
$$

For pose measurements, the identification Jacobian has one row for each of the six pose element of each of the m measurements and one column for each of the p parameters making it a 6m x p matrix. The individual Jacobian matrices of the parameters can be calculated by [6, 31]:

$$
\mathbf{J}_{\alpha_i} = \begin{bmatrix}
  R_{x}^{i,1} \times R_{d}^{i,1,L} \\
  R_{x}^{i,1}
\end{bmatrix} \quad (4.19)
$$

$$
\mathbf{J}_{\alpha_i} = \begin{bmatrix}
  R_{x}^{i,1} \\
  0
\end{bmatrix} \quad (4.20)
$$

$$
\mathbf{J}_{\theta_i} = \begin{bmatrix}
  R_{z}^{i} \\
  0
\end{bmatrix} \quad (4.21)
$$

$$
\mathbf{J}_{\beta_i} = \begin{bmatrix}
  R_{z}^{i,1} \times R_{d}^{i,1,L} \\
  R_{z}^{i}
\end{bmatrix} \quad (4.22)
$$
\[ J^j_{\beta_i} = \begin{bmatrix} R_{y_i} y_{j}^{i-1} \times R_{d_{i-1,L}}^j d_{j}^{i-1} \end{bmatrix} \quad (j = 1, \ldots, m) \] (4.23)

for \((j = 1, \ldots, m)\) where

\[ R_{d_{i,L}}^j = R_i^j P_{i,L}^j \] (4.24)

is the vector connecting the origin of the coordinate frame \(i\) to the origin of the coordinate frame \(L\) \([6, 31]\). Concatenating all individual Jacobian matrices for all \(p\) parameters for the \(j^{th}\) measurement yields 6 x \(p\) matrix:

\[ J^j = [J^j_{\alpha_1}, \ldots, J^j_{\alpha_L}, J^j_{d_1}, \ldots, J^j_{d_L}, J^j_{\theta_1}, \ldots, J^j_{\theta_L}, J^j_{\beta_3}] \] (4.25)

and concatenating this matrix for all \(m\) measurements yields the 6\(m\) x \(p\) generalized Jacobian matrix:

\[ J = \begin{bmatrix} J^1 \\ J^2 \\ \vdots \\ J^m \end{bmatrix} \] (4.26)

### 4.2.2 Identifiability

It is known that some parameters of the model cannot be identified as a result of zero or linearly dependent columns of the matrix \(J\). If a column of the matrix \(J\) is zero, then the parameter corresponding to that column has no effect on the output and thus cannot be identified. Furthermore, the rank of the matrix \(J\) equals to the number of parameters that can be identified \([6]\).

The parameters of the robot that are not identifiable can be obtained using the method presented by Khalil et.al \([29]\). According to this, the identifiable parameters of the robot are determined using a QR decomposition of \(J\) as \([29]\):

\[ J = Q \begin{bmatrix} R \\ 0_{(r-c)\times c} \end{bmatrix} \] (4.27)

where \(Q\) is an \(r \times r\) orthogonal matrix, \(R\) is a \(c \times c\) upper triangular matrix and \(0\) is a \((r-c) \times c\) zero matrix \([29]\). The non-identifiable parameters correspond to the absolute value elements
on the diagonal of the matrix $R$, $| \mathbf{R}(k, k) | (k = 1, \ldots, r)$, that are less than a tolerance value [29]. This tolerance value can be selected as the number of rows times the computer precision [29]. It is also suggested to change the order of the columns of the matrix $\mathbf{J}$ by first placing the parameters whose values can be changed from the control system [6]. After identifying non-identifiable parameters, the corresponding columns of the matrix $\mathbf{J}$ are removed.

We have applied this method using random generated pose measurements. The results are given in Table 4.1. According to this, the parameters $\theta_0$, $d_0$, $\theta_L$ and $d_L$ cannot be identified. The reason for this can be explained as the zero valued $\alpha_1$, $a_1$, $\alpha_L$ and $a_L$ parameters make these parameters’ effect to be grouped with other parameters. The effect of the parameters $\theta_0$ and $\theta_L$ are grouped with $\theta_1$ and $\theta_6$ and the effect of the parameters $d_0$ and $d_L$ are grouped with $d_1$, $d_6$, respectively.

Table 4.1: The identifiable and non-identifiable parameters of the ABB IRB 6600 robot. (I: identifiable parameter, N: non-identifiable parameter, -: no effect on the model)

<table>

</tbody>
</table>

According to Table 4.1, the parameter vector reduces to:

$$\mathbf{w} = [\alpha_1 \ldots \alpha_L \ a_1 \ldots a_L \ d_1 \ldots d_2 \ d_4 \ldots d_6 \ \theta_1 \ldots \theta_6 \ \beta_3]^T$$ (4.28)

The columns of the matrix $\mathbf{J}$ corresponding to the non-identifiable parameters are removed. We will refer to the resulting matrix $\mathbf{J}$ still for simplicity.

4.2.3 Scaling

The position and the orientation components of the pose measurements have different units as millimeters and radians respectively. The accuracy of the measurement system also differs among these components. Thus, the corresponding errors corresponding cannot be compared
directly. In order to overcome this problem, Eq. 4.29 can be scaled by an appropriate weighting matrix \( W \) as [31]:

\[
(w - w^a) = \delta^a = (J^a^T W J^a)^{-1} J^a^T W r
\]  

(4.29)

The measurement system used to obtain pose measurements is capable of giving the standard deviation values of the measured variables. Let the standard deviation of the \( k \)th pose component of the \( j \)th measurement be \( \sigma_{jk} \) for \((k = 1, \ldots, 6)\) and \((j = 1, \ldots, m)\). These standard deviation values can be used on the corresponding diagonal element of the weighting matrix as [31]:

\[
W = \begin{bmatrix}
\left(\frac{1}{\sigma_1^a}\right)^2 & \cdots & \cdots & \cdots & \cdots & 0 \\
0 & \left(\frac{1}{\sigma_2^a}\right)^2 & \cdots & \cdots & \cdots & 0 \\
\vdots & \ddots & \ddots & & & \vdots \\
0 & \cdots & \left(\frac{1}{\sigma^a_k}\right)^2 & \cdots & \cdots & 0 \\
\vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\
0 & \cdots & \cdots & \cdots & \left(\frac{1}{\sigma^a_m}\right)^2 & \\
\end{bmatrix}
\]

(4.30)

4.3 Pose Selection

The success of the parameter identification on finding accurate estimates of the parameters is effected by the measurement noise, the number of measurements and the selection of measurement configurations [36]. A common practice to suppress the measurement noise in order to achieve better estimates of the parameters is to increase the number of measurements used in the identification step. However, a better approach is to select the measurement configurations which will yield good estimates.

The determination of a set of reachable robot measurement configurations that minimizes the effect of the measurement noise on the identification of robot kinematic parameters is the subject of the optimal pose selection algorithms [35]. These measurement configurations are selected using an observability index based on the identification Jacobian matrix. Several observability indices are proposed to be used on robot calibration experiments which are related to the alphabet optimalities of the experimental design literature by Sun and Hollerbach [39]:

- \( O_1 \) is proposed by Borm and Menq [37]. It is the geometric mean of all the singular
values of the identification Jacobian:

\[ O_1 = \frac{\left(\sigma_1 \sigma_2 \cdots \sigma_k\right)^{\frac{1}{2}}}{\sqrt{k}} \tag{4.31} \]

- Driels and Pathre proposed the condition number of the identification Jacobian as the observability index to be minimized [36]. Since all other observability indices are maximized, it is taken as the inverse of the condition number of the identification Jacobian [38]:

\[ O_2 = \frac{\sigma_{Min}}{\sigma_{Max}} \tag{4.32} \]

- \( O_3 \) is proposed by Nahvi and Hollerbach [38]. It is the minimum singular value of the identification Jacobian:

\[ O_3 = \sigma_{Min} \tag{4.33} \]

- \( O_4 \) is again proposed by Nahvi and Hollerbach [38]. It is the square of smallest non-zero singular value divided by the largest singular value of the identification Jacobian:

\[ O_4 = \frac{\sigma_{Min}^2}{\sigma_{Max}} \tag{4.34} \]

In this study, we have selected \( O_1 \) as the observability index for its scale invariant characteristic that also corresponds to the D-optimal design of the experimental design literature [39].

A search algorithm is used to obtain the measurements configurations that maximize the selected observability index amongst a set of all possible measurement configurations. DETMAX, a popular algorithm proposed by Mitchell can be used to find the measurement configurations that maximize the observability index [41]. The basic algorithm follows the procedure below:

1. Start by choosing a set of \( m \) measurement configurations randomly from the possible candidate measurement configurations.
2. Add a new measurement configuration to the current set amongst the candidate set that makes the maximum increase in the observability index.
3. Remove the measurement configuration amongst the current set that makes the minimum decrease in the observability index.
4. Repeat 2 and 3 until the observability index does not increase.

This procedure improves the observability index of a randomly selected set by exchanging measurement configurations at each iteration. The original algorithm also performs a method called excursion that adds or removes new measurement configurations to improve the current set. A variation of the algorithm is proposed by Sun and Hollerbach which starts with a randomly selected set size, improves the set using the exchanging step then adds new measurement configurations until a predefined number is reached [42]. In this study, a variation of the DETMAX is used which first calculates the observability index of the whole candidate set and then removes the measurement configurations that makes the minimum decrease in the observability index until a pre-defined number of measurements is reached. The algorithm then uses this as the initial set and applies the DETMAX algorithm until observability index does not increase. The algorithm then removes a pose within the selected set and searches the candidate set for a better pose that increases the observability index. This algorithm follows the procedure below:

1. Start by choosing all measurement configurations of the candidate set.

2. Remove the measurement configuration amongst the current set that makes the minimum decrease in the observability index.

3. Repeat 2 until a pre-defined number of measurements is reached.

4. Add a new measurement configuration to the current set amongst the candidate set that makes the maximum increase in the observability index.

5. Remove the measurement configuration amongst the current set that makes the minimum decrease in the observability index.

6. Repeat 4 and 5 until the observability index does not increase.

7. Remove a measurement configuration amongst the current set and search for a measurement configuration on the candidate set that further increases the observability index.

8. Repeat 7 for all measurements in the current set until the observability index does not increase.
The major advantage of the algorithm is starting with a selected initial set instead of a random one. The concatenated identification Jacobian in Eq. 4.26 is calculated only once in the first step. It should be noted that as the number of measurements in the candidate set increases, the calculation of the identification Jacobian for all candidate measurements will require more computer time. However, it takes less than three minutes in Matlab by using a PC with Intel 2.4 GHz processor and 3 GBs of RAM for a candidate set of 300 measurement configurations and 24 model parameters which correspond to an 1800 x 24 matrix. This algorithm is used during the simulations and the experiments. The designed graphical interface is shown in Appendix A.
This chapter presents the details and the results of the simulations of the kinematic calibration procedure that is performed by using the developed code and the designed user interface in MATLAB.

5.1 Simulation Parameters

The model of ABB IRB 6600 robot previously developed in the Chapter 3 is used during the simulations. The actual values of the parameters to be identified are generated by adding pre-defined deviations to the nominal parameters of this robot given in Table 3.2. The deviations from the nominal parameters are shown in Table 5.1. These deviations are selected to characterize the identified deviations in previous calibration experiments.

Table 5.1: Selected deviations from the nominal Denavit - Hartenberg and Hayati parameters for simulations.

5.2 Simulation Measurements

In order to obtain the measurement configurations to be used during the simulations, random joint angle configurations are generated. These joint values are then used to solve the end-effector pose using Eq 3.18. A sample measurement sensor is assigned to a selected location to illustrate the conditions to be faced during the experiments. Each generated measurement is checked inside the code to verify if:

- the joint angle values are inside the range of movement of the robot joints shown in Table 3.1.
- the z-axis of the robot end-effector frame inclines towards the sample measurement sensor by an angle of less than 30°.

The need for the first condition is self evident while the second condition is commonly sought by different measurement systems [46]. A total of 300 pose measurements are generated with these specifications.

Three different measurement noise settings are selected typifying different measurement system specifications from low measurement noise to high measurement noise. The measurement noise settings N1 and N3 are toward the both ends of the typical accuracy specifications of the current measurement systems while N2 is in between. The corresponding specifications are shown in Table 5.2. A normally distributed noise is added to the generated measurements with zero mean and a standard deviation value corresponding to each setting.

Table 5.2: Three measurement noise settings used during the simulations. Values represent the standard deviation values.

5.3 Simulation Results

Amongst the generated 300 measurements, a set of 30 pose measurements are selected using the pose selection algorithm discussed in Section 4.3 with random deviations from the nominal parameters. Additionally, 100 pose sets of 30 measurements are selected randomly. Simulations are performed using the three different measurement noise settings.

</table>

The algorithm is run until the change in the sum of errors did not exceed the defined tolerance value or the algorithm reached the tenth iteration, whichever is satisfied first. It is seen that the algorithm is typically converged at the third iteration during the simulations.
The estimated parameters using the selected and the random measurement sets with the three different measurement noise settings are obtained as a result of the identification. The estimation errors of the parameters are calculated subsequently. The estimation errors as a result of using the selected measurement set and the mean, standard deviation, minimum and maximum values of the estimation errors of the 100 randomly selected measurement sets are given in Table 5.3, Table 5.4 and Table 5.5 for the measurement noise settings of N1, N2 and N3, respectively.

Table 5.4: The estimation errors on the parameters after the identification with the selected and 100 random measurement poses for N2 measurement noise settings.

sets. Only the estimation errors of $a_1$, $a_5$, $d_2$, $a_2$, $a_4$ and $\theta_4$ in the selected measurement set are greater than the mean estimation errors of the random measurement sets using the least measurement noise setting N1. The same way, the estimation errors of $a_3$, $a_6$, $d_5$, $a_1$, $a_2$, $a_5$, $a_7$, $\beta_3$ and $\theta_6$ using N2 measurement noise setting and the estimation errors of $a_7$, $d_6$ and $a_3$ using N3 measurement noise setting in selected measurement set are greater than the mean estimation errors of the random measurement sets. Only the estimation errors of $a_2$ for the N1 measurement noise setting and $\theta_6$ for the N2 measurement noise setting are greater than the mean plus the standard deviation value of the estimation errors of random sets.

The expected effect of the measurement noise on the estimation errors of parameters can
also be seen on these tables, in that, as the measurement noise increases, the estimation errors rapidly deteriorate. Especially, using the N3 measurement noise setting, most of the maximum estimation errors of the random sets are greater than the initial errors of the parameters.

After the selected pose measurements are removed from the initial set of 300 generated pose measurements, the remaining set is used to examine the pose errors of the robot end-effector prior to and after the calibration. The results are shown in Table 5.6 for using the selected pose measurements with different measurement noise specifications.

According to the results using the lowest measurement noise settings, the initial errors are reduced for more than 98% for all pose components. For the highest measurement noise, while the improvements on robot pose accuracy significantly dropped, the initial errors are still reduced for more than 70% for all pose components. The worst effected pose components from the measurement noise are the ones representing the orientation. On the other hand, the positioning accuracy improvements from the initial errors are still higher than 85% despite this high measurement noise setting. As an expected result, it can be seen that the improvements on robot pose accuracy greatly decrease as the measurement noise further increases.
CHAPTER 6

EXPERIMENTS

This chapter presents the details and the results of the kinematic calibration experiments that are performed by using the developed code and the designed user interface in MATLAB.

6.1 Experimental Setup

The experiments are performed on an ABB IRB 6600 industrial robot. The nominal Denavit-Hartenberg and Hayati parameters of this robot are derived in the Chapter 3 which are given in Table 3.2.

6.1.1 Measurement System

Leica LTD 500 Laser Tracker is used as the measurement system during the experiments. This laser tracker system uses the absolute distance measurements together with the two angle values from the encoder readings to obtain 3D measurements. In order to obtain full pose measurements from the robot, a Leica T-Mac probe is used which is directly mounted on the robot end-effector using an apparatus as shown in Figure 6.1. The accuracy specifications of the Leica LTD500 laser tracker and the T-Mac probe are shown in Table 6.1.

In order to register the reference coordinate system to the measurement system, the reference guides on the robot body are used. There are a total of four reference guides on the robot and the center of the reference guides are on a circle with its center about on the base frame origin and having a radius of 400 mm which can be seen in Figures 6.3. Concerning the rapid
measurements to be taken from these reference guides, an apparatus that can be mounted inside the reference guide holes is designed according to the dimensions of the reference guide holes shown in Figure 6.4. The apparatus is also designed so that 1.5’ reflectors can be placed on top of it as seen on the Figure 6.2. The calculated positions of the center of these reference guides are shown in Table 6.2. Figure 6.5 shows one of the reference guides, the designed apparatus placed on it and the reflector placed on top of the apparatus.
Figure 6.2: The technical drawings of the designed apparatus for the reference guide holes and the 1.5” reflectors’ position on top of it.

Figure 6.3: The top view of the four reference guides of the robot [44]. Dimensions are in mm and radian.
Figure 6.4: The side-view of the reference guides of the robot [44]. Dimensions are in mm.

6.1.2 Measurements

There were three limitations that are faced during the selection of the poses to be measured:

1. The first joint angle is bounded at 120° rose from the robot workcell conditions.

2. Leica LTD 500 Laser Tracker requires the z-axis of the T-Mac probe to be aligned with the sensor by an angle of less than 45°.

3. The laser beam from the Leica LTD 500 Laser Tracker reaching to the reflector on the T-Mac should not be interrupted while the robot is moving from one pose measurement configuration to the other.

The first and the second conditions are straightforward to check and satisfy while the third condition requires the robot trajectory between the consecutive measured poses to also satisfy the second condition.

In order to meet these conditions, paths to be followed by the robot end-effector are defined in the joint space. The first path is defined using 64 pose measurements and extended to 200 measurements by selecting additional poses on the path. The second path is defined using 84 pose measurements and extended to 325 by again selecting additional poses on the path. The selected poses for the first and the second set of measurements are shown in Figure 6.6 and 6.7, respectively.

The measurements from the first set and the second set are taken two months apart, during which time the robot is continued to be used and even some parts of the robot are replaced. The only nominal parameter of the robot that is changed while the second set of measurements were taken is the $d_7$ resulting from the removal of the 5 mm washers that were between the T-Mac probe and the robot end-effector. Thus, the nominal value of the $d_7$ parameter is taken
as 106.5 mm for the first set of measurements while taken as 101.5 mm for the second set on the parameter identification stage.

The measurements are taken by using a code written in Visual Basic together with the related functions of emScon Software Development Kit (SDK) of Leica Laser Tracker. The Visual Basic for Applications (VBA) inside Microsoft Excel 2007 is used for both creating a basic GUI and for storing the associated measurement data on the worksheets. This proved to be useful for taking the measurements rapidly and loading these measurements to the designed kinematic calibration GUI discussed in Appendix A.

Figure 6.6: The first set of 200 measurements according to the robot base coordinate system. The measurement system is represented by the gray cylinder. The blue lines show the orientation of the z-axes of the poses.
6.1.3 Robot Program

In order to instruct the robot to the joint angle configurations, a robot controller code is written using RAPID language [47]. Each corresponding joint angle configuration is first assigned a to a robot joint target variable using the \textit{jointtarget} data type as [47]:

\begin{verbatim}
CONST jointtarget JointTarget_number:=[[joint angles],[external axes]];
\end{verbatim}

where the \textit{joint angles} and the \textit{external axes} locations are written in order and separated by a comma [47]. These joint targets are then used inside the \textit{MoveAbsJ} command [47]:
MoveAbsJ JointTarget_number,v80,fine,Tool_TMac;

where v80 is the selected speeddata variable which corresponds to 80mm/s speed for the TCP and fine is the zonedata variable which means the joint angle values are instructed without any flyby or tolerance value [47]. Tool_TMac is the tooldata variable that is defined inside the code for the T-Mac as [47]:

PERS tooldata Tool_TMac:=[TRUE,[Position],[Orientation]],

where TRUE indicates that the robot is holding the tool and the Position and Orientation are the translation and rotation of the tool coordinate system with respect to robot wrist coordinate system of the robot in mm and quaternion, respectively.

6.2 Results

The optimal pose selection algorithm is applied on both sets of measurements and 30 poses are selected from each of the set. The measurements for these selected poses are used on the identification stage to obtain the estimated errors on the parameter values. The remaining poses are used to evaluate the pose accuracy of the robot before and after the identification.

The resultant estimated errors on parameters using the selected poses of the first set of measurements are given in Table 6.3. The high value of the estimated error of the parameter d₁ can be explained by the differences of the reference guide holes towards the z axis of the base coordinate system. The estimated error of the parameter θ₆ also includes the orientation error about z axis of the end effector frame and thus, the error associated with the mounting of the T-Mac probe to the robot. This is also the case for the parameter α₇ which is the orientation error about x axis of the end-effector frame. The large estimated error of the parameter θ₂, θ₄ and θ₅ shows the offsets of the joint angle encoder values. The error on the parameter θ₂ was an expected error since the part related to the second joint was reported to be replaced prior to the experiment. There are also large errors on the third link parameters a₄, d₄, α₄ and θ₄ which might be resulted from the effects of heavy loads.

The resultant estimated errors on parameters using the selected poses of the second set of measurements are given in Table 6.4. The robot is put under maintenance after the first set
Table 6.3: The estimated errors of the parameters after using selected pose measurements for the first set of measurements.

</table>

The pose errors of the 170 measurements of the first set and the 295 measurements of the second set that are not used on the identifications can be seen in Table 6.5 and Table 6.6, respectively. It can be seen that the pose errors are greatly reduced on both cases. The first set has larger initial errors compared to the second set that might be resulted from the larger estimated error of the $\theta_2$ parameter on the first set.

Overall, the experiment results show that a significant improvement on the pose accuracy of the robot is achieved by using only 30 measurements. Initial positioning errors are reduced by more than 95% for the first set and 80% for the second set. The same way, initial orientation errors are reduced by more than 84% for the first set and 65% for the second set.

CHAPTER 7

CONCLUSION

Robot calibration is being researched for more than four decades, during which time several methods are proposed. In an industrial point of view, robot calibration should be performed in minimal time and with least effort to decrease the detrimental effects of the production halt. Thus, a robot calibration method needs to be efficient enough to be performed in a factory environment.

Several robot calibration methods are reviewed with the above requirements in concern. Kinematic calibration is decided to be performed on the experiments since the errors associated with other parameters are minimal for the industrial robots as noted in the previous studies and also the errors on the kinematic parameters can be corrected on the robot controller without requiring any additional software or hardware. Full pose measurements from the robot are taken to decrease the time associated with the measurements by obtaining all pose information in a single measurement. Least squares optimization is used on the parameter identification stage for its fast converging characteristic.

A robot kinematic calibration graphical user interface is developed in Matlab to be used for both the simulations and the experiments by coding the necessary mathematical routines for forward geometric model and parameter identification. Identification Jacobian matrices are derived using symbolic expressions in Matlab to be used for any six DoF serial robot. This interface is further supported with additional interfaces for error correction and optimal pose selection.

Kinematic calibration simulations are performed using this interface and the improvements on the pose accuracy of the robot as a result of the calibration are obtained. Through different
measurement noise added to the pose measurements, the negative effects of the measurement noise to the parameter identification are observed. Common optimal pose selection algorithms are reviewed and a modified algorithm is presented. This algorithm is later used during the simulations and experiments.

Kinematic calibration experiments are performed on an ABB IRB 6600 industrial robot. The details of the measurement stage are presented for the collecting of the measurement data. Additional measurements are taken to validate the calibration. According to the results, the initial robot pose errors are reduced by more than 80% for the positioning components and 65% for the orientation components.

In conclusion, an efficient kinematic calibration that complies with the factory environment is presented in this study and it is further supported by simulations and experiments, using novel measurement systems and measurement selection strategies.

7.1 Future Work

The errors on non-geometric parameters are treated as measurement noise in kinematic calibration. While the effects of these parameters on the industrial robot pose accuracy is showed to be minimal, this might not be necessarily true for all robots and even amongst all industrial robots. On the other hand, a full robot calibration that combines all possible error sources is still a complex procedure and it is not practiced often. An efficient method for full robot calibration should be further researched.

Optimal pose selection for kinematic calibration is proved to be valuable in terms of getting better results with the same or even less number of measurements. On the other hand, the pose selection algorithms are still an active field of research. A global method that can be used to determine the optimal poses for different robot geometries will be instrumental for future robot calibration studies.

Self calibrating methods are not widely used on industrial robots while they eliminate the need for an external measurement system. The main challenge for these methods is their hard to apply constraints for the factory environment. A useful strategy to perform these self calibrating methods on limiting conditions of the robot workcell needs to be investigated.
REFERENCES

In order to use for the kinematic calibration experiments and simulations, a graphical user interface (GUI) is designed in MATLAB. The options and the features of this GUI are explained in detail together with its use in later sections.

A.1 Kinematic Calibration Interface

A.1.1 Main Window

The Main Window of the GUI can be seen in Figure A.1. There are four regular buttons and two radio buttons on this window. The two radio buttons are:

- Simulation
- Application

Three regular buttons, Kinematic Parameters, Measurements and Optimization Settings, opens their respective window according to the setting of these radio buttons. In other words, windows designed for simulation will pop up if Simulation radio button is selected and windows designed for application will pop up if Application radio button is selected. Start Calibration button is the final button to be pushed when all the required information are filled on the other windows.
A.1.2 Kinematic Parameters Window

The **Kinematic Parameters Window** of the GUI is designed to specify and display the parameters of the kinematic model. This is done by filling the empty field with the value of the respective parameters. Link lengths and offsets should be specified in millimeters while link twist and joint angles should be specified in radians. In simulation mode, both the nominal values of the kinematic parameters and the specified deviation are needed to be filled on this window. This can be seen in can be seen in Figure A.2. Application mode evidently requires only the nominal values of the kinematic parameters as seen in Figure A.3. These specified parameters can be saved using the Save button and these saved parameters can be loaded using the Load button. The Accept button updates the values of the parameters according to the changes while the Cancel button discards all changes and returns the previous values of the parameters specified before.
A.1.3 Measurements Window

Measurements Window of the GUI is designed to specify and display measurements related data. This is done by filling the empty field with the value of the respective parameters. Positions should be specified in millimeters while orientation and joint angles should be specified in radians. In application mode, this window only changes or displays the pose measurements and the corresponding standard deviation and joint angle values as seen in Figure A.4. In simulation mode, this window additionally displays the measured, calculated and actual pose measurements as can be seen in Figure A.5.
A.1.3.1 **Generate / Load Joint Angles Window**

**Generate / Load Joint Angles Window** can be seen in Figure A.6. This window can be used to generate random joint angle configurations according the range of movement of the joints or load the joint angle data. The upper and lower bounds of the joints can be specified by filling the respective fields. The number of measurements can be specified by selecting the particular number on the drop down list. Pressing the Generate button will close this window and update the **Measurements Window** with the updated measurements. These joint angles are used to calculate the nominal pose data using the nominal parameters and the actual pose data using the deviated parameters. The measured pose data is calculated by adding the generated or the loaded measurement noise to the actual pose data where the measurement noise is taken from the **Generate / Load Measurement Noise Window**. The generated joint angle configurations can be saved using the Save button and this saved data can be loaded.
using the Load button. The Accept button updates the joint angle configurations according to the changes while the Cancel button discards all changes and returns the previous joint angle configurations specified before.

A.1.3.2 Generate / Load Measurement Noise Window

Generate / Load Measurement Noise Window can be seen in Figure A.7. This window can be used to generate random measurement noise according to the selected measurement system specifications. The measurement system can be selected from the drop down list on the top of the window. Pressing Generate button generates measurement noise and fills the table with this information. The generated measurement noise data can be saved using the Save button and this saved data can be loaded using the Load button. The Accept button updates
the measurement noise data according to the changes while the Cancel button discards all changes and returns the previous measurement noise data specified before. These specified measurement data can be saved using the Save button and this saved data can be loaded using the Load button. The Accept button updates the measurement data according to the changes while the Cancel button discards all changes and returns the previous measurement data specified before.

A.1.4 Optimization Settings Window

Optimization Settings Window can be seen in Figure A.8. This window can be used to specify the parameters to be included on the parameter identification stage and the identification algorithm as well as the maximum number of iterations and the tolerance values of the identification algorithm. The parameters can be removed from the identification by simply se-
lecting them from the list. Multiple parameters can be selected by pressing the Ctrl key. The
maximum number of iterations specifies how many times the algorithm will iterate at most.
The termination tolerance of the function specifies the value of the calculated least squares
from Eq 4.3 to be reduced for the algorithm to stop. The same way, the termination tolerance
of the parameters specifies the value of the deviation on each parameter from Eq 4.8 to be
reduced for the algorithm to stop. The two identification algorithms that can be selected using
the radio buttons on the right top place of the window are Gauss - Newton and the Matlab
function *lsqnonlin*. These specified parameters can be saved using the Save button and these
saved parameters can be loaded using the Load button. The Accept button updates the values
of the parameters according to the changes while the Cancel button discards all changes and
returns the previous values of the parameters specified before.

Figure A.6: Generate / Load Measurements window.
A.1.5 Displaying the Results

Pressing the Start Calibration button starts the parameter identification and displays the value of the sum of squares of the error for each iteration on the command window. When either one of the conditions stated on the Optimization Settings Window is met, the algorithm stops and the results are displayed as in Figure A.9. On application mode, the results are the estimated errors on parameters and the final estimated parameters. On simulation mode, the estimation error of the algorithm is also displayed. These results are shown in the Main Window and written on the command window at the same time.
A.2 Pose Selection Interface

The **Pose Selection Interface** of the GUI can be seen in Figure A.10. There are four radio buttons on this window. The two radio buttons for different initial set of measurements are:

- Random IS: The algorithm uses a randomly selected initial set from the candidate set.
- Decreased IS: The algorithm uses a selected initial set using the first step of the algorithm discussed in Section 4.3.

The two radio buttons for different algorithms are:

- Detmax: Detmax algorithm is used for the pose selection as discussed in Section 4.3.
Figure A.9: The results shown in the main window after pressing the Start Calibration button.

- Decreased IS: Modified version of the Detmax algorithm is used for the the pose selection as presented in Section 4.3

The number of measurements on the candidate set and the selected set are specified by filling the empty fields with the value of the respective parameters. The model parameters are also specified by filling the empty fields that appear by pressing the DH Parameters button. Pressing the Start button asks the user if the user wants to load a candidate set or the candidate set will be generated by the interface.

The graphic below is updated each time the observability index is increased. The blue dot represents the observability index value of the initial set, red dots represent the increases made by the Detmax algorithm and the green dots represents the increases made by the modified algorithm.
After the algorithm stops and the resultant set of measurements are obtained, the interface asks the user if the measurements will be saved. Algorithm saves the resultant measurements and the candidate set on a Microsoft Excel worksheet file specified by the user.
